One of the most common initial presentations of acute illness is the onset of symptoms caused by the mediastinal adenitis that commonly accompanies pulmonary infection with *H. capsulatum*. In this setting, affected lymph nodes enlarge, may coalesce, and often compress or obstruct adjacent structures. The illness is generally self-limited, but symptoms may persist for several weeks. Although only anecdotal evidence supports the benefit of treatment, itraconazole may be helpful for patients with active inflammation. An elevated erythrocyte sedimentation rate and CF titer could be considered markers compatible with active inflammation. As also shown in a study involving dogs with mediastinal granuloma,³⁶² adjunctive treatment with corticosteroids sometimes is beneficial,^{157,395,441} and, if effective, results in prompt improvement. If a corticosteroidal agent is used, it should be given in association with an effective antifungal agent because of the risk for dissemination resulting from corticosteroid-induced suppression of cellular immunity. Itraconazole should be continued for 6 to 12 weeks. Although fibrosing mediastinitis is a late complication of histoplasmosis, no evidence has shown that focal mediastinal adenitis is its precursor and that antifungal therapy prevents its occurrence.

Mediastinal granuloma describes a group of mostly caseous lymph nodes that coalesce into a single lesion usually located in the paratracheal region (Fig. 204.7). It is very infrequently seen in children. Lesions often are asymptomatic and discovered as incidental findings in imaging studies. Spontaneous drainage of caseous material may occur and result in fistulous tracts to the esophagus,³⁸¹ bronchi, or skin. In this setting, treatment with itraconazole is appropriate, although its efficacy in this situation is unproven. Operative intervention or stenting of the affected portion of the superior vena cava sometimes is indicated in the event that compression of vital structures occurs and fails to respond to antifungal therapy.¹⁹⁶

Disseminated Infection

Progressive disseminated infections in children require treatment with antifungal agents. Treatment recommendations are summarized in Table 204.3.

Immunocompetent Patients and Immunosuppressed Patients Without Human Immunodeficiency Virus Infection

If not treated with antifungal agents, patients with acute PDH have a mortality rate approaching 100%.^{105,151,231,240} Treatment with amphotericin B results in survival of more than 90% of infants with PDH.^{184,231,293} In contrast to adults, in whom monotherapy with itraconazole for patients

with nonsevere dissemination has been successful,^{104,445} only one report has described the outcome of itraconazole monotherapy in children with disseminated histoplasmosis.⁴⁰¹ Seven children ranging from 2 to 14 years old were treated. A 2-year-old child died “shortly after” treatment was stopped at 1 month. “Marked improvement” was noted in patients treated for 3 months (four patients) and 6 months (one patient), and complete resolution was reported in one patient after 12 months of therapy. Monotherapy with itraconazole is not recommended for disseminated histoplasmosis.⁴⁴¹ Largely on the basis of its demonstrated effectiveness in clinical trials in adults, however, and its ease of administration and tolerability in children, itraconazole is recommended for step-down therapy after induction and clinical improvement with amphotericin B. Serum levels of itraconazole should be monitored along with serum or urine antigen concentrations during therapy and in follow-up to confirm that the fungal burden is decreasing. If amphotericin B is elected as monotherapy, a course of 4 to 6 weeks is recommended. In a retrospective study of 98 patients receiving TNF- α therapy, infliximab and corticosteroid use was associated with higher urine antigen levels and severe disease.⁴¹¹ TNF- α was discontinued in almost all patients, and approximately 50% received amphotericin B for the first 2 weeks of treatment. Itraconazole was administered for 12 months. TNF- α therapy was resumed in one-third of patients with a low rate of disease recurrence (3%). Investigators concluded that resumption of TNF- α therapy appears to be safe in most patients, especially if they have received 12 months of itraconazole.⁴¹¹

Disseminated Infection in Patients With Acquired Immunodeficiency Syndrome

The severity of the initial signs of illness heavily influences the outcome and the treatment regimens selected for patients with disseminated histoplasmosis complicating HIV infection (see Table 204.3). Regimens are determined on the basis of trials conducted in adults. Amphotericin B was effective in 74% to 88% of all cases,^{424,436} whereas patients treated for infections that were sufficiently severe to require hospitalization had a 50% mortality rate.⁴²⁴ In adult patients with moderate to severe disseminated histoplasmosis, liposomal amphotericin B provided a survival benefit compared with that of amphotericin B deoxycholate.¹⁹⁹ Adults with only mild or moderate symptoms were treated successfully with itraconazole monotherapy in 85% of instances.⁴⁴⁵

Recommendations for children are similar to the recommendations for adults; amphotericin B deoxycholate usually is well tolerated in children and is recommended as monotherapy at a dose of 1 mg/kg per day given for 4 to 6 weeks. Alternatively, it may be used for 2 weeks as induction therapy and, after a satisfactory clinical response, discontinued and followed by itraconazole, 5 to 10 mg/kg per day for 12 months. Liposomal amphotericin B, a more costly preparation, may be substituted for the deoxycholate preparation with either regimen in the event of renal complications. Serum, followed by urine, antigen monitoring is recommended during therapy and for 1 year after its completion to confirm clearance and thereafter to assess for relapse. After the completion of therapy, the significance of low levels of antigenuria in the absence of antigenemia and clinical symptoms is unclear and is not an indication to prolong therapy. Prolonged follow-up is recommended in these instances.

Because of a high rate of relapse of histoplasmosis after cessation of antifungal therapy in patients with AIDS complicated by persistently impaired immune function, long-term maintenance therapy (secondary prophylaxis) is recommended.^{198,436,453} In adults with mild to moderately severe disseminated infection, amphotericin B is effective in 81% to 97% of cases,^{260,436} and itraconazole is effective in 90%.^{174,446} Itraconazole is the azole of choice for mildly or moderately ill patients, in whom it may be used as both induction therapy and secondary prophylaxis. Fluconazole is not recommended for secondary prophylaxis but may be considered if patients received amphotericin B as induction therapy or if itraconazole is poorly tolerated or its cost precludes its use.

A prospective observational study of adults with AIDS and disseminated histoplasmosis found it safe to discontinue secondary prophylaxis after 12 months of primary antifungal therapy and the demonstration of sustained immunologic improvement resulting from HAART therapy.¹⁴⁵ Specific criteria for withholding secondary prophylaxis

include negative blood culture results, low *Histoplasma* urine antigen concentration of less than 4 ng/mL, and CD4⁺ T-cell counts greater than 150 cells/ μ L in patients continuing to receive HAART.¹⁶² Primary prophylaxis with itraconazole is effective for patients with AIDS who live in hyperendemic areas (areas in which the incidence of histoplasmosis is more than 5 cases per 100 patients per year).²⁶⁴

Prophylaxis of Immunosuppressed Patients

Clusters of infection occasionally are reported in high-risk populations, sometimes in geographic regions with low background rates.¹²⁶ On the basis of results of a large clinical trial, however, the need for prophylaxis for patients residing in a hyperendemic area and who are undergoing immunosuppression for management of neoplasms, inflammatory syndromes, or transplantation of allogeneic bone marrow or solid organs^{28,372} seems to be low.⁴⁰⁷ Included were patients with CF titers to *H. capsulatum* of 1:8 or 1:16, positive M bands by ID, or radiographic evidence suggestive of past infection (calcified splenic or lung nodules). In contrast, patients receiving TNF- α antagonists seem to be at greater risk for developing disseminated histoplasmosis,^{375,415,467} perhaps attributable to reactivation of latent infection. Although long-term use may appear to be costly, a study from French Guiana showed that primary prophylaxis in a selected patient population could be cost effective.²⁷⁷

Central Nervous System Infection

With the exception of CNS infections that accompany PDH of infancy, isolated histoplasmosis of the CNS in children rarely is seen. Death is almost certain if meningitis is untreated. Treatment is effective in only 20% to 40% of patients with meningitis, and 50% of responders experience relapse after cessation of treatment.²¹⁷

Amphotericin B preparations enter the CSF poorly; however, liposomal amphotericin B concentrations are higher in brain parenchyma.^{111,159,230} It is recommended that patients with CNS infections receive liposomal amphotericin B, 5 mg/kg per day for 4 to 6 weeks, followed by itraconazole for 1 year.

Meningitis was present in 25 of 40 children in a series of PDH.²⁹³ All children received amphotericin B deoxycholate followed by ketoconazole for 3 months. The overall mortality rate in the series was 10%; however, two deaths were in children who failed to complete therapy, and two died within 4 days of presentation, findings suggesting that this regimen cured meningitis in most cases. In the rare setting of a child with meningitis as an isolated infection, recommendations reasonably could include the use of liposomal amphotericin B (in place of amphotericin B deoxycholate) followed by itraconazole for 12 months.

Despite isolated case reports that have documented success with ketoconazole, itraconazole, fluconazole, the combination of itraconazole and fluconazole, and voriconazole,^{402,441} the efficacy of azole monotherapy for the treatment of CNS infections remains inadequately studied. Posaconazole has been used successfully as salvage therapy in a patient after therapeutic failure with prior regimens.^{318,335} The evidence is insufficient to recommend azole monotherapy for CNS infection.

Medical Management of Manifestations That Do Not Require Antifungal Therapy

Several manifestations of histoplasmosis, both common and uncommon, do not require antifungal treatment. Apart from mild primary pulmonary infection, one of the most common is pericarditis. Because it rarely is associated with frank fungal infection of the pericardium, pericarditis usually resolves spontaneously or with nonsteroidal antiinflammatory drugs. Indomethacin usually is effective in rapidly reducing inflammation and can reverse signs of impending cardiac tamponade.⁴⁷⁵ Corticosteroids have been reported to be effective, but, if used, they should be accompanied by antifungal therapy. Rheumatologic symptoms of arthritis, with or without erythema multiforme or erythema nodosum, also respond to nonsteroidal antiinflammatory drugs.³⁶⁶ Fibrosing mediastinitis is a late complication of histoplasmosis, but it occurs occasionally in children. When granulomatous lesions evolve to become diffusely and densely fibrotic, both antifungal and antiinflammatory therapies are ineffective. The clinical and laboratory criteria that are used to assess whether active inflammation is present are inexact, however, and a trial of antifungal therapy often is warranted if clinical features or laboratory

evidence of active inflammation, or both, are present. Treatment with antifungal agents almost always is unsuccessful, but improvement has been reported, albeit rarely.⁴⁰⁶ Presumed ocular histoplasmosis is seen almost exclusively in adults and does not improve with antifungal therapy; its management has been reviewed extensively.⁷¹

Surgical Treatment

Operative intervention rarely is needed to manage patients with histoplasmosis. In a review of 94 patients, 10 to 40 years old, the most common reason for evaluation was obstruction of thoracic structures by mediastinal masses.¹³⁶ Seventy-five patients underwent surgical intervention or endoscopy to relieve obstruction of the pulmonary artery, superior vena cava, bronchus, or esophagus. Recurrent pneumonia, tracheoesophageal fistula, hemoptysis, carinal injury, and broncholithiasis were other indications for surgical procedures.^{136,142,480} Because attempts to excise caseous nodes completely sometimes can damage contiguous structures, the preferable approach is to incise and evacuate debris from such lesions and leave the adherent portion of the capsule intact.^{136,313,461}

Surgery has little place in the management of fibrosing mediastinitis caused by histoplasmosis. The dense fibrous consolidation of mediastinal structures coupled with the hypervascularity of mediastinal tissues renders the risk for development of hemorrhagic and other life-threatening operative complications high. Excisional biopsy carries a prohibitive risk.⁹² Bronchoscopy coupled with coagulation of hyperemic vessels within bronchi in patients presenting with hemoptysis has been useful.²⁵² When calcification has occurred in fibrosing mediastinitis, surgical repair is not feasible, and the fibrosis continues postoperatively. Some success has been achieved with relief of vascular obstruction by percutaneous placement of intravascular stents,^{109,196,398} but complications occur. Prophylactic excision of enlarged mediastinal nodes has not been shown to prevent fibrosis, and patients with large mediastinal lymph nodes who are otherwise asymptomatic rarely progress to develop mediastinal fibrosis.⁴⁴⁷

PROGNOSIS

Histoplasmosis is either unrecognized or self-limited in the majority of persons who acquire this most common of the endemic mycoses. Histoplasmosis causes serious illness in infants, immunocompromised patients, and older persons, particularly those with emphysematous pulmonary disease.⁴¹ The cure rate for children who receive therapy for serious acute manifestations is high. Little prospective information is available about the long-term outcome in acute pulmonary histoplasmosis. A study that examined pulmonary function in six children and their parents after intense exposure found restrictive (three patients) and obstructive (two patients) patterns and a reduction in carbon monoxide diffusing capacity in five of six tested.²¹⁹ At 2 years, a diffusing capacity abnormality remained in three children, and hypoxemia persisted in the most severely affected patient.²⁵⁰ No data that can help predict the occurrence of long-term complications, such as mediastinal fibrosis, are available. Because, by definition, mediastinal fibrosis impairs the function of both the airways and pulmonary vasculature,³⁷⁴ its prognosis is influenced heavily by whether it affects one or both lungs.⁹² The prognosis is poor in the latter instance.

PREVENTION

Complete prevention of histoplasmosis is currently impossible, but reasonable precautions can substantially decrease the exposure to persons with risk factors that predispose them to serious complications should they acquire the infection. Persons with impaired cellular immunity who reside in, or plan travel to, endemic regions should be counseled about the potentially serious consequences of infection. This should include education about areas that are endemic for histoplasmosis, sites likely to be heavily contaminated with *H. capsulatum*, and the circumstances, activities, and events that may aerosolize spores and result in inhalation and infection. Primary prophylactic regimens using itraconazole may be considered for HIV-infected patients with exposure to soil mixed with bird or bat droppings.¹⁷⁰ If such activities are unavoidable, the use of National Institute for Occupational Safety and Health–certified

high-efficiency mask filtration devices should be encouraged; however, effective devices appropriate for use by young children may be unavailable. Sterilization of sites by formaldehyde spray have been attempted, but the toxicity of this agent renders its use undesirable and, in some settings, ineffective. When potentially contaminated sites, such as old or unused structures in which birds or bats have roosted, are disturbed, aerosols that may contain spores can be substantially reduced by thoroughly dampening the areas with water before they are manipulated.²⁷ Although educating and counseling high-risk patients affords some protection against acquiring infection from microfoci, some of which can result in intense exposure, this approach is not helpful in protecting against “sporadic” exposure to contaminated aerosols. For the general population residing in endemic areas, education also is beneficial, particularly for protecting persons whose occupational and recreational activities may increase their risk for exposure to sites likely to be contaminated with *H. capsulatum*.

Although long an active area of research, vaccines directed against any of the endemic mycoses have not yet been developed. Among the challenges in this effort are the need both to target the general population in an extensive geographic region and to develop a vaccine product that provides lifelong protection, perhaps necessitating repeat immunization.³⁷⁸ Investigations in animal models^{183,291,355} are ongoing in an attempt to identify vaccine targets^{96,100,243,472} and to delineate the regulatory elements needed for developing immunity against *H. capsulatum*.^{97,358} Investigations in such models have shown that monoclonal antibodies can alter the pathogenesis of histoplasmosis by targeting host costimulatory molecules or fungal cell surface proteins.²⁹⁰ Another area of inquiry is that of identifying vaccine targets integral to dimorphism, a requisite for the pathogenicity of all the endemic fungi.²⁸¹ Additional efforts have explored the feasibility of developing vaccines against invasive fungal pathogens in the setting of severe immunodeficiency, including persons with CD4⁺ T-cell deficiency.⁴⁷² An animal model has shown that immunization with apoptotic phagocytes that contain heat-killed *H. capsulatum* antigen activated functional CD8⁺ T cells as well as CD4⁺ T cells and protected against infection.¹⁸³ Biodegradable microspheres that contain leukotriene B₄ and cell-free antigens of *H. capsulatum* have been shown to activate murine bone marrow–derived macrophages.¹⁰⁷ A recombinant protein vaccine has been produced from cloned sequences of DNA coding for the cell wall glycoprotein HSP60 and found to be protective in a mouse model against a lethal intravenous inoculum of *H. capsulatum*.¹⁴⁶ This vaccine protected mice in a model of pulmonary infection.

Sporotrichosis

205

Bernhard L. Wiedermann

Sporotrichosis is an infection caused by the fungus *Sporothrix schenckii* species complex that is manifested most commonly as an ulcerating nodule at a site of local trauma, with spread occurring along regional lymphatic channels. Infection of other tissues or widespread dissemination is rare. It is an uncommon problem in children, but young adults seem to be infected more frequently, presumably owing to more frequent exposure to soil, plants, and decaying vegetable matter that harbor the organism. The disease was described first by a medical student, Schenck, in 1898, and most of what is known about the clinical syndrome has been learned from studies of large outbreaks, particularly one occurring in gold miners near Johannesburg, South Africa, in the early 1940s.^{103,118}

ORGANISM

S. schenckii is a dimorphic fungus found principally in decaying vegetable matter or plant debris, although it does not seem to be a plant pathogen. In addition to *S. schenckii* sensu lato, *S. globosa* and *S. brasiliensis* are important pathogens in some geographic areas, with *S. mexicana*, *S. lucrei*, and *S. albicans* having less clinical importance.^{2,19,21,31} Molecular

phylogenetic studies have demonstrated multiple clades that tended to group according to geographic origin.^{21,79} The organism grows well on most culture media and is resistant to cycloheximide. Preferred culture media are Sabouraud glucose agar and blood agar, incubated at 25°C to 27°C. Most isolates grow readily from clinical material within 3 to 5 days, although occasional instances of slow growth have been reported, and cultures should be held at least 4 weeks before being considered negative. Incubation on blood agar at higher temperatures (37°C) allows growth of the yeast phase, which is necessary for specific identification of the organism in culture.⁹⁶

EPIDEMIOLOGY

Most cases of sporotrichosis are reported from Central and South America, especially from Mexico and Brazil, and cases in the United States appear to cluster in the Midwest, particularly along the Mississippi and Missouri river areas.^{50,90} Disease in humans usually results from inoculation of minor wounds by debris containing *S. schenckii*, and gardeners and nursery workers, forestry workers, miners, and other

individuals exposed to contaminated plant materials are at higher risk for acquiring the disease.^{20,25} Disseminated disease has been the initial presentation of some human immunodeficiency virus (HIV)-infected individuals, but the relative paucity of such reports probably reflects the low virulence of the organism.^{4,82} Laboratory personnel working with the organism have become infected after incurring needlestick injuries.¹¹⁶ The large South African epidemic in the gold mines of Transvaal probably resulted from the miners' brushing against rotting timbers in the mines, and a cluster of cases that occurred after a brick-throwing incident in Florida was traced to *S. schenckii* in the packing straw of the bricks.^{99,118} Contaminated hay was the source of one outbreak linked to a Halloween haunted house.³² Pulmonary disease may result from inhalation of spores.⁹⁰ Uncommonly, transmission of disease from animals, particularly domestic cats with cutaneous disease, or from family members occurs.^{34,41,45,94} One adult acquired the disease after being bitten by a squirrel,¹⁰⁰ and a young girl developed cutaneous disease after a rodent bite.⁵⁷ In South America, armadillo hunters are at risk for development of sporotrichosis, but it is acquired from the decaying plant debris in armadillo nests rather than from the animals themselves.⁷⁸ Cats have been implicated in ongoing outbreaks in Brazil.^{2,10,43,104,105} Molecular typing of isolates can be useful in investigations of outbreaks.^{24,83,84}

PATHOGENESIS AND PATHOLOGY

As indicated, the most common mode of acquisition of sporotrichosis is by inoculation of the organism into skin structures, although disease also may develop from inhalation of spores of the organism. The incubation period varies considerably, commonly ranging from 7 to 30 days after cutaneous inoculation but possibly as long as 6 months.⁹⁶ The disease usually remains localized; of the 2825 cases of sporotrichosis in the Transvaal mine epidemic, none had systemic spread.¹¹⁸

S. schenckii, similar to other yeasts, seems to bind specifically to the glycosphingolipid lactosylceramide, which is present on the cell surface of animal cells.⁶¹ This mechanism may be one by which the organism establishes a foothold in the host. Cell-mediated immune responses probably are important for containment of infection. One study documented intact responses in patients with cutaneous forms of the disease, whereas patients with systemic sporotrichosis had impaired cell-mediated immunity.⁸⁹ This study is supported by the observation that systemic disease tends to occur in individuals with underlying diseases or conditions that alter cell-mediated immunity. Deficiencies in toll-like receptor 4 have been suggested as contributing to severity of sporotrichosis.^{9,101} Specific virulence factors also may contribute to likelihood of disseminated disease.^{5,9,115,128}

Histopathologic examination of primary cutaneous lesions usually reveals changes in the epithelium, with hyperkeratosis, parakeratosis, and pseudoepitheliomatous hyperplasia. Intraepidermal microabscesses may be seen as well. In more established lesions, the pathologic process involves the dermis and below, with inflammatory infiltrate extending perivascularly.⁷⁵ The classic lesion on microscopic examination is a granuloma with an asteroid body at the center, although this picture is not pathognomonic for sporotrichosis. The asteroid body is an antigen-antibody complex deposited on the surface of the organism and may consist of several forms.^{74,129} Visualization of fungi in tissue sections often is difficult, even with special staining techniques, because of the paucity of organisms in tissue. They may be seen on Gram stain as gram-positive but irregularly staining bodies, sometimes as cigar-shaped, 3- to 5-µm yeast forms. Periodic acid-Schiff and silver stains probably are better suited for detection of fungi in tissue sections.^{75,96} Immunohistochemical staining techniques may prove superior to standard methods.^{81,87}

CLINICAL MANIFESTATIONS

Sporotrichosis can occur in cutaneous and extracutaneous forms; the cutaneous varieties account for approximately 80% of all cases.⁹⁶ These categories can be broken down further into the organ system involved (Table 205.1).

TABLE 205.1 Clinical Forms of Sporotrichosis

Cutaneous	Extracutaneous
Lymphocutaneous	Osteoarticular
Fixed cutaneous	Pulmonary
	Muscular
	Ocular
	Genitourinary
	Central nervous system

Data from references 1, 53, 55, 70, 90, 97.

TABLE 205.2 Summary of 42 Cases of Pediatric Sporotrichosis

Duration of symptoms before diagnosis	3–10 weeks
Lymphatic involvement	28/47 ^a
Culture positive	39/44 ^a
Relapse after therapy	1/21 ^a

^aNumerator is number of patients positive; denominator is number of patients tested.
Data from references 17, 22, 27, 48, 76, 85.

FIG. 205.1 Cutaneous lymphatic sporotrichosis of both arms. Note the characteristic involvement of lymphatics that drain the sites of the primary lesions. (Courtesy G. Medoff and G. S. Kobayashi.)

Cutaneous Sporotrichosis

Cutaneous disease with *S. schenckii* can be either lymphocutaneous or fixed cutaneous, the latter of which occurs less frequently. In lymphocutaneous cases, the initial lesion appears as a firm, slightly tender subcutaneous nodule. It progresses along local lymphatic channels, with multiple nodules appearing. The lesions typically enlarge and may ulcerate and suppurate (Fig. 205.1). Untreated, they may heal slowly during months or persist; recurrences are frequent. Differential diagnosis includes cutaneous nocardiosis, atypical mycobacterial disease, leishmaniasis, rosacea, syphilis, pyoderma gangrenosum, disseminated *Acanthamoeba* disease, and cutaneous manifestations of other fungal diseases.^{29,68,93,113,126}

The fixed cutaneous form of the disease is just as the name implies, with no evidence of lymphatic spread. The primary lesions are identical to the lesions seen in the lymphocutaneous form. Although some researchers have suggested that sporotrichosis in children, compared with that in adults, is more likely to appear in the fixed cutaneous form, this theory has not been borne out in prior studies. Table 205.2 shows results from six reports of series of cases of sporotrichosis in children. The 60% rate for the lymphocutaneous form may not differ much from

the 90% figure quoted for adults when one takes into account that many pediatric studies are reports of small numbers of cases and may have resulted from selection bias. A large series of patients from Peru documented a disproportionate number of children with facial lesions (86 of 143 children vs. 23 of 95 adults) but did not classify fixed versus lymphocutaneous forms by age.⁸⁸ Fixed cutaneous disease in children has been confused with impetigo.¹⁷ A study from Peru also documented a predilection of children to develop lymphocutaneous lesions on the face and neck.⁷⁷ Risk factors for disease in children in this study included playing in fields, ownership of a cat, and residence in a house with dirt floors. Unusual dermatologic manifestations reported include molluscum-like lesions in a patient with alcoholic liver disease and Sweet syndrome in middle-aged women.^{44,102}

Extracutaneous Sporotrichosis

Sporotrichosis occurring in extracutaneous sites either may be localized (related to an unusual area of trauma) or may represent disseminated disease. In the absence of trauma, the presence of extracutaneous sporotrichosis should raise suspicion of disseminated disease and consideration of immunodeficiency states. Overall, infection of bones and joints is the most common form of extracutaneous disease.¹²⁴ Sporotrichal arthritis usually is an indolent and slowly progressive disease that may occur with or without cutaneous or lymphatic disease, suggesting a hematogenous route of infection for most cases. Diagnosis generally requires synovial biopsy with culture to show the organism.^{106,124} Two studies showed diagnostic delays averaging 17 and 25 months from the onset of symptoms.^{11,26} Sporotrichal osteomyelitis usually occurs with concomitant arthritis, but isolated bone involvement has been recorded. Lytic lesions and periosteal changes are noted most frequently.^{52,124}

Pulmonary sporotrichosis seldom occurs with cases of disseminated disease and probably develops after inhalation of spores, as with primary pulmonary histoplasmosis.⁹⁰ The presence of cavitory lesions in the upper lobes often leads to a diagnosis of tuberculosis, and fungal culture of sputum, bronchoscopic specimens, lung tissue, or gastric aspirate usually is needed to establish the diagnosis.^{35,90,122} In addition to cavitory disease, noncavitory radiographic patterns also are reported.⁶ Pleural involvement is uncommon (three of 47 cases in one review), and complications, such as massive hemoptysis, rarely occur.^{37,56,90}

Sporotrichosis has been found to involve virtually every organ system in the body as part of disseminated disease.¹²⁴ Most commonly, underlying immunodeficiency states, such as diabetes, prolonged steroid therapy, alcoholism, immunosuppressive therapy, and acquired immunodeficiency syndrome (AIDS), are present.* In one Brazilian cohort of HIV-infected patients with sporotrichosis, 7 of 21 developed disseminated disease and 2 had meningitis.⁴² Ocular and endocardial infection has been reported as well.¹¹² Disseminated disease, including meningitis, also has been reported as part of immune reconstitution syndrome in AIDS patients.^{46,54} Fungemia in the absence of disseminated disease has been documented in one otherwise healthy adult with a lysis-centrifugation blood culture system, and laryngeal and cutaneous sporotrichosis has been reported in a healthy child.^{67,69} Dissemination in patients with neoplasia seldom occurs. One child with chronic granulomatous disease and sporotrichal lymphadenitis has been reported.¹²¹

DIAGNOSIS

A high index of suspicion is necessary to establish the diagnosis of sporotrichosis. In the largest outbreak in the United States, which occurred in 1988 among horticulturists and forestry workers, only 15% of cases were diagnosed at the time of initial presentation to a physician.²³ Culture is the gold standard for diagnosis of sporotrichosis. Although organisms occasionally are seen on pathologic specimens, the yield is low enough to render biopsy unnecessary. If the diagnosis is suspected, scrapings of cutaneous lesions for culture should be sufficient to establish the diagnosis.⁹⁶

A skin test antigen has been available for many years, but as with the histoplasmin skin test for histoplasmosis, it is useful mainly as an epidemiologic tool. Polymerase chain reaction may prove useful for

diagnosis in the future.⁶³ Serodiagnosis has been explored in a few studies. Immunoprecipitation or commercially available slide latex agglutination can be useful when material for culture is difficult to obtain or cultures are negative, such as with sporotrichal meningitis.^{30,107} In the ongoing Rio de Janeiro outbreak, an enzyme-linked immunosorbent assay detecting immunoglobulin G antibody to the SsCBF cell wall antigen has shown promising results.¹² Antibody titers in cerebrospinal fluid tend to decrease with successful therapy, and such tests might prove useful for monitoring of response to therapy.^{13,107} Western blot testing has been used to detect sporotrichal antibody.¹⁰⁸ Using a crude antigen preparation, Scott and Muchmore¹⁰⁸ determined that detection of antibody to three antigens, 32 kDa, 40 kDa, and 70 kDa, seems to be sensitive and specific for diagnosis of active sporotrichosis. Patients with extracutaneous disease seemed to form antibody to a greater number of *S. schenckii* organisms than did patients with cutaneous disease. Further studies of the immune response in sporotrichosis should enable development of better serodiagnostic tests than those that now are routinely available.

TREATMENT AND PROGNOSIS

Sporotrichosis may resolve spontaneously, but treatment is indicated in most circumstances.^{8,91} The Infectious Diseases Society of America has published practice guidelines for management of patients with sporotrichosis in 2007, reviewed and deemed current in 2013.⁶⁶

Heat applied to the site of cutaneous disease has been reported anecdotally to cause resolution of lesions in patients in whom medical therapy was contraindicated.^{47,97,119} One prospective study showed good results with use of benzene pocket warmers for heat therapy of facial lesions in children.⁵⁹ Surgical removal of infected skin and soft tissue has been used, but skin grafting may be required.¹⁶ This form of treatment usually is unnecessary with the availability of medical management except possibly for some cases of pulmonary infection (particularly if it is confined to one lobe) and other extracutaneous disease.^{26,52,90} Hyperthermia remains an option for treatment of sporotrichosis in pregnancy, in situations in which other agents may be contraindicated.⁶⁴

A saturated solution of potassium iodide (SSKI), a proteolytic agent for which the mechanism of action against sporotrichosis is unclear,^{65,72} can be used for uncomplicated sporotrichosis. The *in vitro* growth of *S. schenckii* is not inhibited appreciably by iodide, but free iodine has a marked inhibitory effect on growth.¹²³ The small amount of free iodine in a saturated solution of potassium iodide may be sufficient to cause resolution of disease. The pediatric dosage of a saturated solution of potassium iodide is empiric; it usually is given three times daily in juice or milk, starting at a low dose (e.g., 1 to 2 drops per year of age, up to 5 drops) and increasing the dose during the course of several days to a maximum of 30 to 40 drops per dose.^{22,76,85} For younger children, lower dosages may be acceptable.^{76,92} Treatment is continued until a few weeks after all lesions have resolved. Adverse reactions, such as salivary gland swelling, excessive lacrimation or salivation, nausea, vomiting, and abdominal pain, may resolve with temporary cessation of therapy followed by reinstitution at a lower dosage. SSKI currently is only an alternative treatment for lymphocutaneous and cutaneous forms of the disease.⁶⁴

In vitro susceptibility testing is not used widely, and results may not always agree with clinical response.^{98,120} The Clinical and Laboratory Standards Institute has proposed a microdilution test, whereas the European Committee for Antimicrobial Susceptibility Testing uses a similar assay with a different inoculum and test medium.⁹ Breakpoints have not been established.

Itraconazole, an oral azole derivative, is the drug of choice for treatment of cutaneous, lymphocutaneous, and osteoarticular forms of sporotrichosis.^{15,60,61,64,110} Restrepo and colleagues⁹⁵ showed clinical cures in all 17 patients with cutaneous forms of sporotrichosis treated with itraconazole (100 mg/day), with no major side effects. Borelli¹⁴ reported a treatment failure, however, in a patient treated with 100 mg/day, who subsequently responded when the dose was increased to 200 mg/day. Systemic disease also has been treated with itraconazole with favorable clinical responses, although all information is from cases in adults.^{7,71,86,110,125} Unfortunately, itraconazole resistance in *Sporothrix* has been reported.^{49,114}

*References 1, 38, 51, 58, 62, 70, 111, 117, 124, 127.

Intravenous amphotericin B remains the drug of choice for treatment of patients with disseminated or severe sporotrichosis.^{64,73,124} Duration of therapy in children has not been studied, but recommendations are to begin with liposomal amphotericin B at 3 to 5 mg/kg per day, with stepdown to itraconazole after clinical improvement to complete 12 months of total treatment.⁶⁶ On occasion, intraarticular amphotericin B is used to treat sporotrichal arthritis if response to other therapy is poor.³³ Amphotericin B therapy in patients with pulmonary sporotrichosis is less effective than with other forms of sporotrichosis, which has prompted many clinicians to use a combined medical-surgical approach.^{66,90} Itraconazole is an alternative therapy and may be useful for long-term suppression.⁶⁶ Amphotericin B seems to be effective in treating sporotrichal meningitis when it is given early in the course of the disease, but adjunctive therapy with flucytosine or rifampin might be helpful.¹⁰⁶ Itraconazole and fluconazole also may have roles in treating meningitis.^{60,66} Immunosuppressed individuals may require lifelong suppressive therapy with itraconazole to prevent recurrence, depending on the degree of immunosuppression and severity of disease.⁶⁶

S. schenckii does not seem to be particularly susceptible to ketoconazole in vitro, and clinical experience with ketoconazole treatment of sporotrichosis has been mixed.^{18,28,109} Possibly, relatively large doses of ketoconazole are needed to produce a good clinical response. Terbinafine, an allylamine, has looked promising in clinical studies.^{39,40,60} Posaconazole has looked promising in a murine model of sporotrichosis, including in combination with amphotericin B.^{36,80} Melanin production by *Sporothrix* strains appears to lessen the effects of antifungal agents such as terbinafine.³

Prognosis for cutaneous forms of disease is excellent, but the extracutaneous forms are associated with significant morbidity and mortality, in part related to the underlying conditions predisposing these patients to disseminated disease. Many cases of osteoarticular disease result in permanent disability.²⁶

PREVENTION

The key to prevention of sporotrichosis is the elimination of exposure to the organism, particularly with regard to skin surfaces and mucous membranes. Usually, elimination of exposure can be accomplished by the use of protective clothing during high-risk activities, such as working with sphagnum moss or other decaying, moist plant material.^{20,23} Nursery

workers should be educated about the hazards and early signs of sporotrichosis, and physicians and veterinarians should be aware of the uncommon circumstances of spread of the infection from family members and domestic cats. The epidemic in the Transvaal gold mines was stopped when timbers in the mine shafts were sprayed with a fungicide.¹¹⁸ Although reporting of individual cases of sporotrichosis is not required in the United States, reporting of clusters of cases can aid epidemiologic investigations and stop the spread of the disease.

Mucormycosis and Entomophthoramycosis

Rachel L. Wattier • William J. Steinbach

Mucormycosis and entomophthoramycosis are invasive fungal infections once grouped together as “zygomycosis” based on a previous common classification within the phylum Zygomycota. However, they differ greatly in epidemiology and disease syndromes. Mucormycosis is the second most common invasive mold infection in immunocompromised hosts and tends to be rapidly progressive with extremely high mortality. Entomophthoramycosis occurs most commonly as indolent subcutaneous infection affecting immunocompetent hosts in tropical and subtropical regions.

Molecular phylogenetic analyses have since determined that the organisms previously grouped into the phylum Zygomycota did not share common evolutionary relationships, and thus the phylum has been abandoned. Currently those taxa conventionally classified in Zygomycota are now distributed among the new phylum Glomeromycota and four subphyla.⁸¹ Causative agents of mucormycosis, within the order Mucorales, are grouped in the subphylum Mycoromycotina,

and causative agents of entomophthoramycosis, within the order Entomophthorales, are grouped in the subphylum Entomophthoromycotina (Fig. 206.1).

It is now preferred to use the names “mucormycosis” to refer to disease caused by members of the order Mucorales (not by organisms from the genus *Mucor* as the name might suggest) and “entomophthoramycosis” for disease caused by members of the order Entomophthorales. As molecular phylogenetics continues to progress, these taxonomic definitions and clinical names may be subject to further change. This chapter focuses on mucormycosis, with a brief description of entomophthoramycosis.

MUCORMYCOSIS

Paltauf is credited with the first description of mucormycosis in humans in 1895 in his paper entitled “Mycosis Mucorina,” describing a case of disseminated mycosis in a cancer patient.¹¹⁹ The first English-language

FIG. 206.1 Taxonomy of human pathogens causing mucormycosis and entomophthoromycosis. Not all disease-causing species are represented. The orders Mucorales and Entomophthorales were previously grouped together in the class Zygomycetes, within the phylum Zygomycota; they are now classified in separate subphyla.

description of the disease appeared in 1940 when Wade and Matthews described a case of cutaneous mucormycosis of the face.¹⁶²

ORGANISMS

The most common causative genera of Mucorales in humans are *Rhizopus*, *Mucor*, and *Lichtheimia* (formerly *Absidia*), which account for 70% to 80% of reported cases, with *Cunninghamella*, *Apophysomyces*, *Saksenaea*, *Rhizomucor*, *Cokeromyces*, *Actinomucor*, and *Syncephalastrum* species individually accounting for fewer than 1% to 5% of reported cases.⁴⁹ These organisms grow readily on common laboratory media but are inhibited by cycloheximide. Mucorales on solid media demonstrates rapid growth of woolly colonies, often with spores seen as tiny dark dots to the naked eye. Hyphae characteristically are large (10–30 µm in diameter), aseptate, and often twisted or ribbonlike. The lack of septation and the tendency of hyphae to branch at right angles usually serve to distinguish them from *Aspergillus* species, which are septate, smaller, and branch at acute angles.⁵ Genera usually are differentiated from one another by examination of mycelia. Speciating the members of Mucorales is often difficult using conventional methods but can be improved by molecular methods.³⁷

EPIDEMIOLOGY

Causative agents of mucormycosis are ubiquitous in nature and found in all parts of the world in soil and decaying organic material such as vegetation, bread, seeds, fruits, and manure. They are also occasionally

isolated from the hospital environment, and acquisition of mucormycosis among immunocompromised hosts may be facilitated by hospital construction activities.^{77,137,171} Recent hospital-acquired cases have been linked to contaminated linens and to a dietary supplement.^{22,39,155} Mucormycosis has also been reported in association with environmental exposure during natural disasters.^{115,170}

Mucormycosis is rare, with population-based incidence estimates of 1.7 cases per million population in the United States in 1992–93, and 0.09 cases per 100,000 population in France in 2001–10.^{11,130} However, the incidence of mucormycosis in France increased by 7.3% per year, and mucormycosis-associated mortality increased by 9.3% per year between 2001 and 2010.¹¹

Compared with other invasive mold infections, mucormycosis can affect hosts with a wider range of predisposing factors. In addition to the traditional immunocompromised risk groups (individuals with hematologic malignancy, transplant recipients), mucormycosis can affect individuals with diabetes mellitus and other metabolic disorders, breakdown of skin or soft tissue integrity such as in burn patients or surgical patients, and prematurity (Box 206.1).⁸⁷ Cases are occasionally reported in immunocompetent hosts with no known risk factors.^{6,9,18,70}

The multicenter Transplant-Associated Infection Surveillance Network (TRANSNET) found that mucormycosis was rare, but second to invasive aspergillosis as a cause of invasive mold infection. Among 1208 invasive fungal infections (IFIs) identified among 1063 solid-organ transplantation (SOT) patients, mucormycosis accounted for only 2% of cases, compared with invasive aspergillosis (19%) and other non-*Aspergillus* molds (8%).¹²¹ The median time from transplantation to diagnosis of mucormycosis

Trauma or surgery
Burns

was 312 days. Of 983 IFIs diagnosed among 875 hematopoietic stem cell transplantation (HSCT) patients from the same network, 8% of cases were mucormycosis, whereas 43% were invasive aspergillosis.⁷⁵ Median time from transplantation to diagnosis was 135 days, later than invasive aspergillosis.

In most large case series and systemic reviews of mucormycosis in adults and children, the most common causative genera are *Rhizopus* and *Mucor*, identified in approximately 50% and 20% of cases, respectively.^{72,134,177} European cohort studies report higher frequencies of *Lichtheimia* (formerly *Absidia*), accounting for up to 29% of cases.^{87,145} Less common organisms such as *Apophomyces elegans* and *Saksenaia vasiformis* occur more frequently in patients whose main predisposing factor is trauma.^{70,92}

The most frequently reported predisposing conditions for mucormycosis vary based on setting and time period. In a systematic review of 929 reported cases from 1855 through 2003, diabetes mellitus was the most common predisposing factor, seen in 36% of cases.¹³⁴ Contemporary case series show greater disease burden among patients with hematologic malignancy, who account for approximately 45% to 60% of cases.^{72,87,126,145} Overlapping risk factors are commonly observed; for example, patients with hematologic malignancy who have undergone HSCT are receiving immunosuppression and may also have hyperglycemia or iron overload.⁷² In children, prematurity is an important risk factor, seen in 17% of cases in a large systematic review.¹⁷⁷

Some centers have reported a rising incidence of mucormycosis among HSCT recipients and patients with hematologic malignancy.^{74,101} Breakthrough infections with mucormycosis have been increasingly reported among patients receiving voriconazole as antifungal prophylaxis and as empirical, preemptive, and targeted antifungal therapy for invasive aspergillosis.^{62,74,102,143} One hypothesis is that voriconazole, because of its lack of activity against the Mucorales, has exerted selective pressure favoring the emergence of mucormycosis. However, a longitudinal study evaluating the incidence of mucormycosis within well-defined populations of HSCT and SOT patients at multiple transplantation centers showed a stable incidence of mucormycosis within those populations before and after availability of voriconazole, although the absolute number of cases increased in direct proportion to the growing number of transplant recipients.¹ Increases in the reported number of cases of mucormycosis may in fact be related to increases in the number of immunocompromised individuals at risk and transplantation of higher risk individuals, with voriconazole as a surrogate marker for other risks associated with the development of mucormycosis.

PATHOGENESIS AND PATHOLOGY

Mucormycosis usually is acquired after inhalation of spores from environmental sources, and the organisms may colonize the sinuses

and nasopharynx. Occasionally, mucormycosis results from cutaneous inoculation of spores secondary to trauma, as has occurred with contaminated elastic adhesive tape^{31,47} and hospital linens,^{22,39} as well as ingestion of contaminated food or supplement products.^{89,114,155} Following inhalation of airborne spores, primary infection usually develops in the upper or lower respiratory tract and may spread by contiguous or hematogenous dissemination. Disseminated disease most commonly arises from the lungs and spreads hematogenously to the central nervous system (CNS), kidneys, gastrointestinal tract, and heart. Dissemination can also occur from cutaneous or subcutaneous sites of infection. Person-to-person transmission has not been documented.

The immune status of the host is fundamental to production of disease. In normal hosts, agents of mucormycosis are killed by mononuclear cells and neutrophils through the generation of oxidative metabolites and cationic peptide defensins.^{34,165} The neutrophil appears to be the primary component of the immune response against these organisms and may prevent germination of inhaled spores.³³ Both neutropenia and qualitative deficiencies of neutrophil function are associated with an increased risk for mucormycosis.^{134,177} *Rhizopus oryzae* (also known as *R. arrhizus*) displays less susceptibility to neutrophil-mediated oxidative damage, compared with *Aspergillus fumigatus*.²⁰ In addition, corticosteroid treatment impairs the ability of macrophages to prevent germination of spores and is an important clinical risk factor for mucormycosis.^{134,164,177}

Diabetes mellitus, in particular diabetic ketoacidosis, is one of the most common underlying conditions in patients with mucormycosis. Serum from patients with diabetic ketoacidosis does not inhibit the growth of *Rhizopus* spp., but serum from those same patients after treatment of the ketoacidosis shows inhibitory properties similar to those of normal human serum.⁴⁶ Hyperglycemia and acidosis impair neutrophil chemotaxis and oxidative responses needed to damage *R. oryzae* hyphae.²³ Additionally, acidosis alters availability of serum iron, likely by reducing ability of transferrin to sequester iron in serum; available iron is another important factor altering virulence of mucormycetes.⁷

Multiple observations support a role for iron availability in pathogenesis of mucormycosis. Paradoxically, patients treated with the iron chelator deferoxamine have a markedly increased risk for mucormycosis, as demonstrated by the tendency for deferoxamine therapy to result in progression of both natural and experimental mucormycosis.^{14,15,28,30,140,157} This phenomenon has been particularly observed in patients undergoing hemodialysis.^{14,13,174} Studies in experimental models suggest that deferoxamine serves as a siderophore for *Rhizopus* spp., making previously unavailable iron available for use, with resultant increased fungal growth and increased mortality in a guinea pig model.^{12,30,157} Enhanced iron uptake in the presence of deferoxamine appears to be a unique virulence factor among the Mucorales because the effect of deferoxamine is less pronounced for *A. fumigatus* and is minimal for *Candida albicans*.¹² Enhanced iron uptake and virulence of mucormycosis is unique to deferoxamine and has not been observed with other iron chelators.

The hallmark of histologic examination of mucormycosis is vascular invasion with resultant thrombosis and tissue necrosis and accompanying acute and chronic inflammation. Most of the clinical findings of progressive disease can be related to these effects on blood vessels. Septic emboli may affect all parts of the body. Perineural invasion also occurs commonly.⁴⁵ In the rhinocerebral form, the disease may progress along nerve roots during intracranial spread. Although relatively sparse, hyphal forms may be seen in tissue on routine hematoxylin and eosin staining more commonly than with silver or other special fungal stains¹³² (Fig. 206.2).

CLINICAL MANIFESTATIONS

The clinical forms of mucormycosis are best considered by type of organ system involvement (Box 206.2). The primary site of infection at the time of initial diagnosis varies as a function of the host population (Table 206.1). The most common forms of mucormycosis are rhinocerebral, pulmonary, and cutaneous.¹³⁴ Historically, rhinocerebral infection was reported to be the most common form (39% of cases), but in contemporary series, a greater proportion of cases have been

FIG. 206.2 Mucormycosis caused by *Rhizopus* species. Observe the varied morphologic features of the aseptate hyphae and large size. (Hematoxylin and eosin, original magnification $\times 64$.)

Hematopoietic stem cell transplantation	Pulmonary, disseminated, rhinocerebral
Solid-organ transplantation	Sinus, cutaneous, pulmonary, rhinocerebral, disseminated
Intravenous drug use	Cerebral, endocarditis, cutaneous, disseminated
Malnutrition	Gastrointestinal, disseminated
Deferoxamine therapy	Disseminated, pulmonary, rhinocerebral, cerebral, cutaneous, gastrointestinal
No underlying condition	Cutaneous, pulmonary, sinoorbital, rhinocerebral, gastrointestinal

From Kontoyiannis DP, Lewis RE. Invasive zygomycosis: update on pathogenesis, clinical manifestations, and management. *Infect Dis Clin North Am*. 2006;20(3):581-607.

pulmonary (28–46%), corresponding to the increase in disease burden among individuals with hematologic malignancy.^{72,87,134,145} Other forms of invasive mucormycosis include gastrointestinal, disseminated, and other rare presentations.

Rhinocerebral Mucormycosis

The acute rhinocerebral form of mucormycosis, including sinus and sinoorbital infection, occurs most often in the setting of diabetes mellitus or hematologic malignancy.^{134,145} Compared with invasive aspergillosis, mucormycosis is more likely to involve the orbit, versus only the sinuses.¹⁵² Rhinocerebral mucormycosis spreads from the nares, palate, or sinuses to the paranasal sinuses, and then to the retroorbital region and brain

by contiguous or hematogenous spread. Symptoms include facial pain, edema, and headache, with facial anesthesia in advanced infection.¹²² Physical examination reveals brownish, blood-tinged nasal discharge, proptosis, or cranial neuropathies. Involved tissues become red, then violaceous, and finally black as vessels are thrombosed and tissues undergo necrosis.¹²² Involvement of the orbital region can be manifested as proptosis or orbital edema, and ocular or optic nerve involvement can be suggested by pain, blurring, diplopia, or loss of vision.^{122,147} Manifestations of invasive cerebral involvement include seizures,¹¹⁶ encephalopathy, or stroke.¹⁰⁵

Pulmonary Mucormycosis

Pulmonary mucormycosis may develop as a result of inhalation or by hematogenous or lymphatic spread. Pulmonary mucormycosis is the most common manifestation among patients with hematologic malignancy and HSCT patients.^{72,87,134,145,176} Patients with pulmonary mucormycosis often present with fever, cough, chest pain, and rapidly progressive dyspnea, although findings can initially be subtle, with isolated fever.¹⁵⁰ Angioinvasion results in necrosis of lung tissue, which may lead to cavitation and hemoptysis. Massive pulmonary hemorrhage may result from vascular erosion.^{53,169} Chest radiographs and computed tomography (CT) scans may reveal a focal consolidation, isolated masses, nodules, cavitation, or wedge-shaped areas of infarction.^{66,76,106,150} Because of the lack of inflammatory cells that are capable of infiltrating the lung in neutropenic patients, however, radiography may not be dramatically abnormal.

Distinguishing pulmonary mucormycosis from invasive pulmonary aspergillosis is a clinical challenge, but certain epidemiologic, clinical, and radiographic features favor mucormycosis. Among patients with cancer, pulmonary mucormycosis is associated with previous exposure to voriconazole or other *Aspergillus*-active agents.²¹ Among HSCT patients, acute graft-versus-host disease and history of invasive aspergillosis are associated with subsequent mucormycosis.¹³¹ Clinical presentation with concomitant sinusitis and pulmonary disease is more often associated with mucormycosis.²¹ Radiographic features suggestive of pulmonary mucormycosis include the presence of multiple nodules (≥ 10) and, to a lesser degree, pleural effusions on CT scans.²¹ The reversed halo sign on CT, a central ground-glass opacity surrounded by a halo of dense consolidation, is seen more frequently with pulmonary mucormycosis than with other invasive mold infections (19% vs. <1% in one study, and 54% vs. 6% in another).^{66,163} In contrast, pulmonary aspergillosis is associated with more airway invasive findings, such as clusters of centrilobular nodules, peribronchial consolidation, and bronchial wall thickening.⁶⁶

Some atypical and more indolent presentations of pulmonary mucormycosis include chronic infection with constitutional symptoms in relatively immunocompetent hosts.¹⁰⁶ Rarely, fungus balls have been noted within a preexisting lung cavity.⁸³ Hypersensitivity pneumonitis caused by *Rhizopus* spp. has been described in farm workers as well as Scandinavian sawmill workers (so-called wood-trimmer's disease).⁴⁰

Skin and Soft Tissue (Cutaneous) Mucormycosis

Cutaneous (also referred to as skin and soft tissue) mucormycosis represents approximately 20% of reported cases in adults and a slightly higher proportion of pediatric cases.^{134,177} Primary cutaneous infection usually occurs at the site of trauma, burns, adhesive dressings, or invasive procedures in immunocompromised hosts.^{25,47,71,154,172,173} Skin and soft tissue infection is the primary manifestation of mucormycosis that is reported among immunocompetent hosts, and typically is due to contamination of wounds with organic material.^{18,70,92,115} Among neonates, the skin is a common point of entry, with involvement of adhesive tape, monitor leads, or central venous access sites predominating. Premature infants represent most of the neonatal cases.^{96,133} Secondary cutaneous disease may be seen with hematogenous dissemination.⁷¹ Primary disease may be very invasive locally and by direct extension affect adjacent bone and tissue. With vessel invasion, frankly disseminated disease may arise.

Primary cutaneous disease typically begins with a lesion that appears erythematous and indurated and progresses with ulceration and necrosis to form a black eschar (Fig. 206.3). In contrast, cutaneous disease arising

FIG. 206.3 Cutaneous mucormycosis in a child with neutropenia.

secondarily from disseminated disease usually manifests as nodular subcutaneous lesions, which may ulcerate. Skin and soft tissue infections associated with trauma can vary in presentation depending on the type and extent of original injury, with manifestations from superficial to deep, sometimes presenting as necrotizing fasciitis.^{92,115}

Gastrointestinal Mucormycosis

Gastrointestinal mucormycosis is a rare manifestation that probably results from ingestion of fungal spores, either from the environment or from colonized upper airways. Occasionally, hematogenous or direct extension routes result in intestinal tract involvement. Immunosuppression, malnutrition, prematurity, uremia, and underlying gastrointestinal disease, such as typhoid fever or amebiasis, are predisposing factors.^{35,110,114} Gastrointestinal mucormycosis is the most common clinical manifestation among neonates, representing two-thirds of neonatal cases.¹⁷⁷ Most gastrointestinal disease in neonates is seen in premature neonates, sometimes occurring in association with progressive necrotizing skin lesions and sometimes manifesting with necrotizing enterocolitis.^{175,177}

All sites along the intestinal tract can be involved. Historically, the stomach and colon were the most common sites, but a recent review of cases in immunocompromised hosts suggests that localization varies based on host susceptibility.^{35,114} Intestinal disease was more common among HSCT patients and patients with hematologic malignancy, and reported cases increased over time; gastric localization was more common among SOT patients.³⁵ Fever and nonspecific abdominal pain with hematemesis, hematochezia, or melena may occur. Dissemination to other sites may occur by hematogenous routes. Perforation after bowel wall necrosis is common. Among the forms of mucormycosis, gastrointestinal infection is associated with the longest diagnostic delays, and diagnosis is frequently made only at autopsy.³⁵

Disseminated Mucormycosis

Disseminated mucormycosis, with infection occurring at two or more noncontiguous sites, is reported in 15% to 20% of cases.^{72,87,134,145} Disseminated infection is most likely to occur in severely immunocompromised hosts, such as those with active hematologic malignancy or allogeneic HSCT patients.¹³⁴ Patients who develop mucormycosis in the setting of deferoxamine therapy may also present with widely disseminated infection, often without an apparent primary site.^{13,14,174} Clinical manifestations vary depending on the sites involved and the extent of tissue invasion. Disseminated infection often stems from pulmonary infection as the primary site, with the central nervous system as a frequent secondary site. A subacute form of disseminated disease with a protracted but fatal course has been reported.¹¹⁷ Disseminated mucormycosis is associated with extremely high mortality and is often not apparent premortem.^{64,158}

Miscellaneous Forms of Mucormycosis

A variety of case reports of mucormycosis involving isolated areas of the body are found in the literature and include reports of endocarditis,^{109,138,178} brain abscess,¹³⁴ peritonitis,^{17,112,124} osteomyelitis,⁴¹ mediastinitis,¹⁰⁴ tracheitis,¹⁴¹ corneal infection,¹⁵¹ otitis externa,¹⁵¹ superior vena cava syndrome,¹⁶ and renal disease.⁹⁹ Common to these disease manifestations is some type of local trauma or surgery that results in a ready access site for invasion of fungal organisms. Outcome varies highly and depends on the underlying condition of the host as well as the extent of disease.

DIAGNOSIS

The diagnosis of mucormycosis is established by identification of a causative organism by culture, direct microscopy, or histopathology in a patient with compatible clinical findings.^{26,32,144} A high index of suspicion is needed to make the diagnosis, with appropriate radiographic imaging and sampling of tissue from affected clinical sites. Securing diagnostic samples from internal sites such as the lung can be challenging because of risks for invasive procedures in unstable and thrombocytopenic patients. Sites such as skin and sinuses are more amenable to sampling, leading to more definitive diagnoses in cutaneous and rhinocerebral infections. Even with adequate tissue samples, the diagnosis of mucormycosis can be difficult to establish owing to limitations of culture and histology. Because of these diagnostic challenges and the rapidly progressive nature of the disease, empiric therapy should be started as soon as mucormycosis is suspected.

Cultures may be negative in a large portion of cases, even when *Mucorales* hyphae are visualized in tissue, because the aseptate hyphae are prone to shearing during tissue processing. Many specimens, including blood, sputum, gastric fluid, or nasal swabs, are either difficult to culture or of minimal diagnostic value, and invasive mucormycosis is ideally diagnosed with tissue biopsy and culture.⁴³ Cultures from bronchoalveolar lavage fluid may grow *Mucorales* but are of lower yield than cultures from tissue. The presence of *Mucorales* in cultures does not always represent active infection. The spores from asexual reproduction are easily airborne and may be laboratory contaminants; some patients may be colonized. One study showed that 65% of patients with positive cultures for *Mucorales* did not meet criteria for proven or probable IFI.⁸⁶ Patients with hematologic malignancy were more likely to meet criteria for disease, whereas patients with chronic respiratory diseases were less likely to meet criteria and had a benign clinical course.⁸⁶

It can be difficult to definitively identify *Mucorales* by histopathology because the appearance of hyphae may not be characteristic in damaged or necrotic tissue, or there may be insufficient hyphae present to characterize the morphology. It is not possible to identify *Mucorales* to the species level based on histopathology alone. Several methods show potential to improve identification of *Mucorales* within tissues, including immunohistochemistry,⁶⁷ polymerase chain reaction (PCR)–based methods,^{3,37,38} and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS).³⁶ Many of these methods are technically specialized, and only *Mucorales* PCR and pan-fungal PCR (based on ribosomal RNA sequence) are available for clinical use.

There is no established noninvasive method to diagnose mucormycosis. β -D-Glucan and galactomannan are not released by *Mucorales*, and no other serum biomarkers have been identified for mucormycosis. There may be a future role for novel methods to improve diagnostic yield from less invasive sampling techniques. A study of PCR and high-resolution melt analysis conducted on bronchoalveolar lavage samples showed improved detection of probable pulmonary mucormycosis compared with culture and histopathology, but included only a small number of patients with mucormycosis.⁹³ One study showed that circulating *Mucorales* DNA was detectable in serum by PCR from 9 of 10 patients with proven or probable mucormycosis, with the first positive sample preceding diagnosis by 3 to 68 days.¹⁰⁸ None of the 10 healthy controls evaluated had detectable circulating *Mucorales* DNA. In a subsequent study, 36 of 44 (81%) patients with proven or probable mucormycosis had detectable circulating *Mucorales* DNA, with the first positive at a median of 9 days (range, 0–25 days) before diagnosis.¹⁰⁷

Another investigational diagnostic method is the detection of Mucorales-specific T cells in peripheral blood. In a study of 204 patients screened during chemotherapy for hematologic malignancy, 21 (10.3%) had detectable Mucorales-specific T cells.¹²⁵ Six of these patients had clinical evidence of IFI and were distinguishable from patients without IFI based on high production of interleukin-10 and interleukin-4.¹²⁵ Although these noninvasive methods appear promising, they will require further evaluation to determine their performance characteristics in diverse clinical populations. There is currently a study in progress to establish a registry and biobank of mucormycosis cases and controls to facilitate development of novel diagnostic methods.¹⁶⁸

TREATMENT

General Principles

Of overall great importance is the combination of early and aggressive surgical excision of necrotic lesions, reversal of predisposing conditions (immune dysfunction, neutropenia, hyperglycemia, acidosis), and early antifungal therapy. Because tissue infarction is a prominent feature, removal of devitalized tissue is critical because antifungals alone, especially in the setting of continued immunosuppression, will not elicit cure.^{91,123} All necrotic-appearing tissue should be removed, and often patients require repeated surgical procedures for removal of devitalized tissue. Among 22 patients with rhinocerebral mucormycosis from a French registry, all of the patients who had complete local control of disease survived to 90 days, whereas 90-day survival was only 25% in the patients without complete local control.¹⁶¹ Duration of therapy for mucormycosis is highly individualized; guidelines recommend continuation of therapy until resolution of clinical and radiographic manifestations and restoration of immune function.^{26,144} Patients who remain immunocompromised may require long-term secondary prophylaxis to prevent recurrence.

Amphotericin B Formulations

Lipid formulations of amphotericin B, either liposomal amphotericin (L-AmB) or amphotericin B lipid complex, given at high doses (at least 5 mg/kg per day, up to 10 mg/kg per day) are recommended as first-line therapy for mucormycosis.^{26,144} Conventional amphotericin B deoxycholate has been used historically but is highly nephrotoxic. Although different doses of lipid amphotericin B formulations have not been directly compared with one another in humans, higher doses of L-AmB were associated with better disease response in a murine model.⁹⁴ A single-arm clinical trial (AmBizzo) of high-dose (10 mg/kg) L-AmB (combined with surgery in 71% of cases) in 40 patients with mucormycosis showed favorable clinical responses in 36% of patients at week 4 and 45% at week 12.⁸⁸ However, doubling of creatinine occurred in 40% of patients.⁸⁸ Delayed amphotericin B–based therapy (treatment \geq 6 days after diagnosis) was associated with a two-fold increase in mortality (83% vs. 49%) in one study, emphasizing the importance of early appropriate therapy.¹⁹

Triazoles

Most triazoles, including fluconazole and voriconazole, have no activity against Mucorales. This point is critically important because voriconazole is an excellent antifungal against invasive aspergillosis, but has no clinical activity in mucormycosis. Whether or not exposure to voriconazole actually enhances virulence of mucormycosis is debated. Prior exposure to voriconazole is associated with occurrence of breakthrough mucormycosis,^{62,74,102,143} and some studies have shown higher mortality in patients with mucormycosis who previously received voriconazole.⁷² Data from animal models show enhancement of *Rhizopus* and *Mucor* virulence following exposure to voriconazole.^{10,84} However, a multicenter longitudinal cohort study of HSCT and SOT patients showed stable disease severity and mortality of mucormycosis over time, before and after availability of voriconazole.¹

Posaconazole has activity against Mucorales and has shown efficacy in salvage therapy for patients intolerant of or unresponsive to amphotericin B formulations.^{156,159} Reported clinical response rates range from 66% to 79% in salvage therapy.^{50,156,159} These rates cannot be accurately compared with the success rate for primary therapy with L-AmB because patients who survive long enough to qualify for salvage therapy studies

likely have more slowly progressive disease and may have benefited already from surgery or reversal of underlying conditions. Additionally, reporting bias likely inflates the success rates in case reports and series.

Posaconazole has not been systematically evaluated as primary monotherapy and should be used with caution, particularly in early phases of therapy.^{26,144} Posaconazole has slower in vitro killing⁸⁰ and is active against a narrower range of clinical isolates⁴ compared with amphotericin B. In vitro susceptibility to posaconazole among clinical isolates of *R. oryzae* and *Mucor circinelloides*, two of the most common causative agents of mucormycosis, is poor, with only 64% of *R. oryzae* isolates and none of six *M. circinelloides* isolates showing susceptibility.⁴ Studies in murine models show zero or limited activity of posaconazole against experimental infection caused by *R. oryzae* and *M. circinelloides*.^{29,61,135,139} Bioavailability of the posaconazole oral suspension is unreliable, particularly in patients with mucositis or diarrhea.^{78,79,90,153} New oral tablet and intravenous formulations are now available but have not yet been evaluated in children. Posaconazole is currently recommended for salvage or stepdown therapy and secondary prophylaxis of mucormycosis, but not for primary antifungal therapy.^{26,144}

Isavuconazole is a triazole with a broad spectrum of activity, including Mucorales. It shows favorable pharmacokinetics compared with other triazoles, with good oral bioavailability and linear elimination kinetics.¹³⁶ It is given orally or intravenously as a prodrug, isavuconazonium sulfate, which is converted to the active drug in vivo. In a murine model, it showed similar efficacy to amphotericin B in protecting against experimental mucormycosis.⁹⁸ In a single-arm open-label clinical trial (VITAL), adults with mucormycosis (21 receiving primary treatment, 11 refractory to other agents, 5 intolerant to other agents) treated with isavuconazole showed 11% partial response and 43% stable disease at day 42.¹⁰³ For assessment of the secondary endpoint, all-cause mortality, patients receiving isavuconazole as primary therapy were matched to contemporaneous controls from a registry (FungiScope) who received primary therapy with amphotericin B formulations. All-cause mortality at day 42 was similar in cases treated with isavuconazole (33%) compared with controls treated with amphotericin B–based therapy (39%).¹⁰³ Isavuconazole is now licensed for primary therapy of mucormycosis based on this study, but its ultimate place in therapy will depend on further clinical assessments. Pharmacokinetics and safety of isavuconazole have not yet been defined in children.

Combination Therapy

Poor outcomes of mucormycosis treated with monotherapy have prompted investigation of combination antifungal therapy; the data on this approach are conflicting. Although echinocandins lack significant activity against Mucorales, there is biologic plausibility for synergy in combination with amphotericin B–based therapy. *R. oryzae* expresses the gene encoding for the 1,3- β -D-glucan synthase complex, and its enzyme activity is inhibited by caspofungin.⁵⁷ Furthermore, caspofungin uncovers β -D-glucan in the cell wall of *R. oryzae*, enhancing activity of human neutrophils against the organism.⁸⁵ Murine models have shown benefit of combination amphotericin B and echinocandin therapy in experimental mucormycosis.^{60,148} A clinical study of polyene-echinocandin combination therapy for mucormycosis found a benefit in patients who were predominantly nonneutropenic with diabetic ketoacidosis as the main predisposing factor.¹²⁹ However, this study was retrospective and small, with only 6 patients receiving combination therapy, compared with 31 who received amphotericin B–based monotherapy.

The effect of amphotericin B and posaconazole combination therapy in murine models is unclear, with one study suggesting benefit and another showing similar responses to L-AmB with or without posaconazole.^{61,135} A report from two large prospective registries described responses to therapy in 32 patients with mucormycosis who were treated with combination L-AmB and posaconazole, mostly as salvage therapy.¹¹⁸ At a median 3-month follow-up time, clinical improvement was seen in 18 patients (56%); the study was not controlled.

Subsequent observational studies incorporating strategies to control for bias and confounding have called the benefit of combination therapy into question. A longitudinal study showed that 90-day survival among HSCT and SOT patients with mucormycosis was not significantly different between two time periods, 1995–2003, during which amphotericin

B–echinocandin therapy was used in 5% of cases, and 2004–11, during which it was used in 31% of cases.¹ Another study used propensity scores to adjust for likelihood of receiving initial combination therapy (defined as two or more of L-AmB, posaconazole, or caspofungin) among patients with hematologic malignancies and mucormycosis.⁸² There was no apparent impact of combination therapy on mortality, with or without propensity score adjustment. At this time, guidelines for treatment of mucormycosis suggest that combination therapy may be used for salvage of refractory cases, but there is insufficient evidence to support its use as primary therapy.^{26,144}

Adjunctive Therapies

Iron chelation with agents other than deferoxamine has been evaluated as adjunctive therapy for mucormycosis and shows benefit in animal models.^{59,58} A clinical trial of 20 patients randomized to adjunctive deferasirox versus placebo for treatment of mucormycosis (DEFEAT Mucor) showed higher mortality at 90 days in the deferasirox arm.¹⁴⁹ However, the trial was small and baseline characteristics were unbalanced, with higher frequency of active malignancy, neutropenia, and corticosteroid therapy in the deferasirox arm. At this time, clinical guidelines for mucormycosis do not recommend the use of deferasirox, particularly in patients with hematologic malignancies, but further studies are needed to determine whether there is a role for adjunctive deferasirox in other at-risk populations.^{26,144}

Hyperbaric oxygen therapy has been used as an adjunct to surgical and antifungal therapy for some patients with mucormycosis in an attempt to limit the extent of gangrene and tissue necrosis.^{27,44,68,127} The increased oxygen pressure achieved with hyperbaric therapy seems to improve the ability of neutrophils to kill organisms and inhibit fungal growth in vitro.⁸ Although this regimen is apparently promising, the number of patients evaluated with this form of treatment is much too small to permit any firm conclusions on benefit.

The role of other adjunctive therapies for mucormycosis has not been well studied. Granulocyte transfusions, or cytokines that enhance phagocytic activity, such as interferon- γ and granulocyte-macrophage colony-stimulating factor, have been used occasionally to treat patients with mucormycosis.^{2,48,146} Case reports have indicated favorable outcomes in patients treated with these adjunctive therapies,^{2,146} but further studies are warranted to determine their role in therapy.

PROGNOSIS AND PREVENTION

The disease site and host factors are key determinants of prognosis for mucormycosis. The reported mortality rate is highest for disseminated disease (100%), followed by gastrointestinal (85%), cerebral (79%), pulmonary (76%), and rhinocerebral (46%) disease.¹³⁴ Localized cutaneous disease is associated with a low mortality rate of 10%. Significant risk factors for mortality include disseminated disease, renal failure, active malignancy, monocytopenia at diagnosis, and lymphopenia at diagnosis.^{19,70,95,134} Patients who undergo surgery and those who receive early amphotericin B–based therapy are significantly more likely to survive.^{19,56,72,134} Neutrophil recovery is also a favorable prognostic factor.¹⁹ Among children, age younger than 1 year is associated with higher mortality.¹⁷⁷ Mucormycosis is sufficiently uncommon that primary prophylaxis is not routinely recommended.^{26,144}

ENTOMOPHTHORAMYCOSIS

The name of the order Entomophthorales comes from the Greek and means “insect destroyer,” highlighting the fact that many species in this order are insect pathogens. Few species are associated with human disease, which typically is seen in immunocompetent patients residing in tropical and subtropical areas of the world. Infections caused by Entomophthorales are usually chronic, subcutaneous, and localized without blood vessel invasion.¹⁴²

ORGANISMS

The Entomophthorales organisms that cause human infection are confined to two genera, *Conidiobolus* and *Basidiobolus*. *C. coronatus* and *C. incongruus* are the major disease-causing species of *Conidiobolus*.

Basidiobolus ranarum is the only human pathogen of the *Basidiobolus* genera; previously reported disease-causing species *B. haptosporus* and *B. meristosporus* are now known to be identical to *B. ranarum*.¹⁴² Growth of Entomophthorales occurs readily on solid media, as flat, gray, or pale-yellow waxy colonies with velvety white mycelia on the surface. The hyphae may or may not have septae.

EPIDEMIOLOGY

Entomophthoramycosis occurs sporadically, with most cases reported in Africa and Asia, although cases have also been reported in Europe, North America, and South America.¹⁴² Since the mid-1990s multiple cases of gastrointestinal basidiobolomycosis have been reported from Arizona; reasons for emergence there are unclear.¹⁶⁰ In a case-control study including seven adult patients in Arizona, infected patients tended to be more likely to use ranitidine and to have resided in Arizona for a longer time compared with controls.¹⁰⁰

Members of Entomophthorales commonly are found in feces of reptiles, amphibians, and other animals as well as in decaying vegetable matter.¹⁴² The mode of acquisition is not determined but is hypothesized to be through minor trauma, inhalation, or ingestion of environmental spores.¹⁴²

PATHOGENESIS AND PATHOLOGY

The organisms causing entomophthoramycosis are of extremely low virulence, as manifested by the rare occurrence of these infections despite the ubiquitous nature of the fungi. Given their low virulence, some have proposed that infection with Entomophthorales is acquired during a state of transient immunosuppression, such as during a viral illness, or from repeated exposure.¹⁴²

Conidiobolus spp. are characteristically associated with rhinofacial infections, and *B. ranarum* is more often associated with subcutaneous infections of the back, buttocks, and lower extremities.¹⁴² However, both genera have been reported to cause both forms of subcutaneous disease.^{52,54} Additionally, invasive and fulminant infection resembling mucormycosis has been reported to occur in immunocompromised hosts.^{166,167}

Histopathologic examination of affected tissues shows areas of acute and chronic inflammation in association with broad hyphal elements that may or may not display septations. The hyphae are more visible with hematoxylin and eosin staining than with more specific fungal stains.¹⁴² The tendency for vascular invasion typical of mucormycosis does not occur with entomophthoramycosis, and tissue necrosis is uncommon. A characteristic pathologic feature of the subcutaneous forms of entomophthoramycosis is the Splendore-Hoeppli phenomenon, consisting of organisms with inflammatory infiltrate surrounded by eosinophilic material in a stellate pattern.¹⁴² The eosinophilic material is thought to consist of antigen-antibody precipitate on the organisms. The Splendore-Hoeppli phenomenon is not pathognomonic of entomophthoramycosis, however, and has been seen in other chronic fungal infections, as well as chronic bacterial and parasitic infections.¹⁴²

CLINICAL MANIFESTATIONS

Chronic Rhinofacial Entomophthoramycosis

Chronic rhinofacial entomophthoramycosis, also called *entomophthoramycosis conidiobolae* because most infections are caused by *Conidiobolus coronatus*, is an indolent subcutaneous infection involving the nasal and paranasal structures.^{55,111,113} Typically, painless bilateral intranasal swelling and obstruction eventually progress to invasion of the sinuses and nodular soft tissue swelling of the face, unaccompanied by fever or pain. Firm subcutaneous nodules can become deeply attached and feel anchored to underlying tissues.¹⁴² Symptoms commonly persist for weeks or months. Deep tissue progression is unlikely to occur, but spread to the orbits, central nervous system, and mediastinal structures has been reported.¹⁴²

Chronic Subcutaneous Entomophthoramycosis

Chronic subcutaneous entomophthoramycosis, also known as *entomophthoramycosis basidiobolae*, is similar to chronic rhinofacial disease

with the exception that the lesions usually are on the trunk or extremities. The usual etiologic agent is *B. ranarum*. Painless subcutaneous nodules may progress to invade deeper soft tissues, and massive soft tissue swelling may develop. In contrast to subcutaneous lesions caused by *Conidiobolus* spp., subcutaneous nodules caused by *B. ranarum* are typically not anchored to underlying tissues and are freely mobile.^{128,142} They are often misdiagnosed initially as soft tissue sarcomas.¹²⁸ With rare exceptions, most cases of subcutaneous entomophthoromycosis are slowly progressive, but they can cause lymphatic obstruction and elephantiasis and are occasionally deeply invasive.^{65,142}

Gastrointestinal Basidiobolomycosis

Gastrointestinal basidiobolomycosis is an extremely rare condition resulting from *B. ranarum* infection of the gastrointestinal tract. Clinical features include fever, abdominal pain, leukocytosis, and eosinophilia; sometimes an abdominal mass is palpable.^{42,120,160} Initial misdiagnosis as inflammatory bowel disease or colon cancer is common.⁴²

DIAGNOSIS

Diagnosis of entomophthoromycosis relies on clinical suspicion and supportive findings from tissue biopsy. Histopathology shows typical findings including the Splendore-Hoeppli phenomenon. As with mucormycosis, cultures may have lower yield because hyphae are easily damaged during tissue processing.^{42,142} Molecular methods may be used to identify organisms in tissues when cultures are negative.¹⁴² Serodiagnosis by immunodiffusion is possible, but tests are not widely available for clinical use.^{63,69}

TREATMENT

Evaluating therapy for this group of diseases is difficult because of their rarity and occasional reports of spontaneous resolution. Many agents have been tried, alone or in combination, with variable success, including potassium iodide, triazole antifungals, amphotericin B, and trimethoprim-sulfamethoxazole.^{24,128,142} Most isolates of *Conidiobolus* and *Basidiobolus* spp. have relatively high minimum inhibitory concentrations (MICs) to amphotericin B.⁵¹ *Conidiobolus* displays relatively high MICs to fluconazole, posaconazole, and itraconazole, whereas *Basidiobolus* tends to have lower MICs to these agents. A systematic review of therapies for *Conidiobolus* infections was unable to identify a clear benefit of any specific antifungal agent.²⁴

Surgery is thought to be important for resolution of gastrointestinal basidiobolomycosis.⁵ Surgery may be beneficial in early stages of rhinofacial entomophthoromycosis, but in advanced stages lesions may not be resectable.^{24,142} Although surgery is frequently reported for subcutaneous entomophthoromycosis, some have reported frequent recurrence of disease after surgery.¹²⁸ Successful adjunctive therapy with hyperbaric oxygen has been reported.^{44,97}

PROGNOSIS AND PREVENTION

Mortality caused by entomophthoromycosis is unlikely to occur, but morbidity and disfigurement are common. Adverse outcomes are associated with underlying immunocompromising conditions, atypical clinical presentation (e.g., orbital involvement with rhinofacial disease, visceral or perineal involvement with subcutaneous entomophthoromycosis), and absence of the Splendore-Hoeppli phenomenon on pathology, perhaps reflecting a poor immune response.^{24,128,142} Among infections caused by *Conidiobolus* spp., mortality is higher in the setting of facial elephantiasis, female gender, and infections caused by non-*coronatus* species.²⁴ Specific means for preventing disease are unavailable because so little is known about factors predisposing individuals to these chronic infections.

Fusariosis and Scedosporiosis

Damian J. Krysan • Melanie Wellington • William J. Steinbach

Fusarium and *Scedosporium* are species of molds that cause hyalohyphomycosis. Hyalohyphomycoses, although not as common as invasive aspergillosis or mucormycosis, are invasive fungal infections caused by nondematiaceous molds that lack cell wall melanin and thus are nonpigmented, in contrast to phaeohyphomycoses, which are fungal infections caused by pigmented molds. In profoundly immunocompromised patients, fusariosis and scedosporiosis are increasing in prevalence and are associated with high mortality. Recent guidelines on the diagnosis and management of invasive mold infections in immunocompromised hosts have included sections on *Fusarium* and *Scedosporium*,^{5,47,73} and the first clinical practice guideline focused on management of *Fusarium* and *Scedosporium* disease was published in 2014.⁷³

INFECTIONS CAUSED BY *FUSARIUM* SPECIES

Microbiology and Pathogenesis of Infection

Molds of the *Fusarium* genus are saprophytic environmental fungi that are well recognized as plant pathogens and, increasingly, as the cause of human infections.^{18,51,54} *Fusarium* species are among the organisms that cause hyalohyphomycosis by virtue of their characteristic tissue form consisting of hyaline-like branching or nonbranching hyphal elements.¹⁸ The most common clinical *Fusarium* isolates include *Fusarium solani* (50%), *Fusarium oxysporum* (20%), *Fusarium moniliforme* (10%), and *Fusarium verticillioides* (10%).^{18,51,54} In immunocompetent patients, *Fusarium* is the most common cause of fungal keratitis; *F. oxysporum* is the predominant organism.^{18,51,54,78} Keratitis can progress

to endophthalmitis, but this is more common in immunocompromised patients.⁵⁴ In addition, *Fusarium* is an important cause of onychomycosis.⁵² Invasive fusarial disease can develop in immunocompetent patients who have had tissue breakdown due to trauma or burns⁵³ and in patients who have indwelling catheters, such as for vascular access, hemodialysis, or peritoneal dialysis.²¹ Among immunocompromised patients, *Fusarium* is an emerging cause of infection⁵⁵; *Fusarium* species are now the third most common cause of mold infections in hematopoietic stem cell and solid organ transplant recipients after *Aspergillus* and Mucorales.^{30,46,58}

A limited set of case series describing invasive mold infections in children provides insights into the epidemiology of pediatric fusariosis. First, a prospective international study of invasive mold infections in children by the International Pediatric Fungal Network (IPFN) between 2007 and 2011 identified 4 children with invasive fusariosis among 131 total cases of invasive mold infection.⁷⁷ Second, Schwartz and colleagues reported a 15-year experience of invasive fusariosis at a single center that included five cases over that period.⁶⁶ Finally, an outbreak of fusariosis occurred in a children's cancer hospital in Brazil.³⁶ Over a 16-month period, a total of 10 confirmed cases of invasive fusariosis were identified; in the 5-year period before the outbreak period, no cases had been observed. The source of the outbreak was thought to be the water system, and instillation of 0.2- μ m filters seemed to lead to resolution, although the last case occurred nearly 1 year after the instillation.

The portal of entry for most cases of disseminated *Fusarium* infections is the respiratory tract, but access to the patient may also be gained through vascular catheters.^{1,7,20,51,55} *Fusarium* species have a propensity for vascular invasion, resulting in thrombosis and tissue necrosis, as well as for dissemination to extrapulmonary tissues.⁵³ One of the characteristics of *Fusarium* infections compared with other molds such as *Aspergillus* is that there is a high rate of fungemia. Many isolates of *Fusarium* species are capable of producing a yeast-like synanamorph when the microconidia enlarge; then, instead of germinating to form hyphae, these give rise directly to unicellular propagules, called adventitious sporulation (Fig. 207.1). This leads to a rapid dissemination and could explain the higher rate of positive blood cultures compared with other molds, such as *Aspergillus* species.⁷ Another explanation for the high rate of positive blood cultures is the potential ability of *Fusarium* organisms to sporulate by forming phialides and phialoconidia within the human body.⁶⁵

Risk Factors and Clinical Syndromes

One of the most common fusarial infections of immunocompetent patients is keratitis.^{18,54,78} Indeed, fungal keratitis is one of the most important causes of monocular vision loss worldwide. *Fusarium* species are the dominant causative agent of fungal keratitis in tropical regions, whereas yeast are more common in temperate regions. In addition, an

outbreak of fusarial keratitis occurred in 2006 in contact lens wearers^{13,29} in association with a specific contact lens solution (ReNu with MoistureLoc) and resolved after the product was voluntarily removed from the market. Onychomycosis is a second common manifestation of fusarial infection in immunocompetent hosts and typically results from environmental contamination of the great toenail, presenting as proximal subungual onychomycosis.⁷⁴

In immunocompromised patients, invasive fusariosis shares many characteristics with invasive aspergillosis, including the risk factors of neutropenia and corticosteroid exposure, which results in a similar bimodal distribution (before and after engraftment) in hematopoietic stem cell transplant recipients.^{7,54,55} Among allogeneic hematopoietic stem cell transplant recipients with fusariosis, other risk factors identified in multivariate models include severe graft-versus-host disease and an underlying diagnosis of multiple myeloma.^{43,54,55}

The incidence of fusariosis appears to be affected by both geography and season. A multicenter retrospective study found that fusariosis occurred more frequently in the summer and autumn months than in the winter and spring months. The infections were more likely to occur during the rainy season, which was thought to be due to the dispersal of the soil-borne fungi by the rain and wind.⁵¹ As discussed earlier, increasing numbers of reports have suggested that this organism may also be acquired through hospital water supplies.¹

Invasive fusariosis in hematopoietic stem cell transplant recipients most frequently is manifested as invasive pulmonary disease, with dissemination to the extrapulmonary organs in as many as 70% of cases.⁴³ Widespread skin lesions occur in approximately 70% of cases (Fig. 207.2), in sharp contrast to invasive *Aspergillus*, which has skin manifestations in less than 5% of cases.⁵³ Cutaneous lesions may take several forms, including painful, discrete, erythematous nodules; raised keratotic masses; and violaceous papules and nodules that break down to form black necrotic centers.⁵³ Although these skin lesions are typically larger, more erythematous, and more painful than those caused by *Aspergillus* species, the appearance is not specific for fusariosis. Other filamentous fungi, such as *Acremonium* and *Alternaria* species, can cause

FIG. 207.1 Characteristic cutaneous lesions of disseminated fusariosis. (Courtesy Dr. John Perfect, Duke University.)

FIG. 207.2 Silver stain of a knee biopsy specimen from a patient with disseminated fusariosis showing adventitious sporulation. The arrow points to the phialide, and the arrowhead points to the released conidium. (Courtesy Wiley Schell, Duke University.)

similar skin lesions, in which the characteristic yeast-like structures are noted on histopathologic examination. However, culture of skin lesions was the most important basis for the diagnosis of fusariosis in a series of immunocompromised patients⁵³; therefore, in this population of patients, biopsy specimens of all skin lesions should be taken and evaluated by both fungal culture and histology.

Localized cutaneous infections can also occur in immunocompromised patients; the most common manifestations are onychomycoses and cellulitis. Because localized infections may progress to involve cellulitis and may lead to disseminated infection, *Fusarium* isolated in nail cultures should not be dismissed as a contaminant in an immunocompromised patient.^{3,7,51}

Diagnosis and Therapy

The clinical presentation of fusariosis has no features that reliably distinguish it from other invasive fungal infections. In addition, no specific diagnostic methods exist for fusariosis except for histopathology and the microbiologic examination of blood, sputum, and biopsy tissues. Major clues to *Fusarium* infections include blood cultures positive for mold and the presence of the characteristic skin lesions. In contrast to aspergillosis, *Fusarium* species are isolated from the bloodstream in approximately 50% of patients.⁵³ Non-culture-based methods have been developed for the diagnosis of invasive fungal disease by the detection of galactomannan and (1→3)-β-D-glucan in the serum.^{34,56} Like most other fungi, *Fusarium* species are generally positive in the (1→3)-β-D-glucan assay.⁵⁶ Some *Fusarium* species have been reported to contain galactomannan in vitro, and a limited case series found that nine of 11 patients with fusariosis had positive galactomannan assays.^{45,72}

In general, *Fusarium* species are relatively resistant to most clinically used antifungal agents on the basis of in vitro studies. Among currently available agents, voriconazole and amphotericin B are the most active.⁵⁴ Keratitis is typically treated with topical natamycin. Although initial studies of topical voriconazole indicated that it may be an alternative, a large clinical trial found that it is inferior to natamycin for the treatment of fungal keratitis largely owing to its reduced efficacy against *Fusarium*.⁸⁰ Echinocandins have very little in vitro activity against *Fusarium*.⁷⁶ Compared with other fungi, the minimum inhibitory concentrations (MICs) for amphotericin B-based agents are high (0.5–8 μg/mL); accordingly, animal studies indicate minimal therapeutic responses to lower doses of amphotericin B formulations.^{23,39}

Reports have indicated that voriconazole and posaconazole have good in vitro and in vivo activity against experimental *Fusarium* infections.^{23,39} Currently, both voriconazole and posaconazole are licensed by the Food and Drug Administration for salvage treatment of fusariosis.⁴⁸ A retrospective analysis of 73 cases of fusariosis treated with voriconazole suggested that voriconazole has efficacy that is comparable to the historical response rate reported for patients treated with amphotericin B.³⁸ Combination drug studies have also been reported, with in vitro synergy demonstrated with a combination of amphotericin B and either 5-flucytosine or rifampin.⁶⁸ Similarly, the combination of amphotericin B and caspofungin has been shown to yield synergistic or additive interactions with no antagonism observed in vitro.³⁷ In addition, there have been a number of case reports of the successful use of combinations of antifungals in the treatment of patients.³⁷

High-dose intravenous amphotericin B lipid formulation has historically been regarded as a first-line option.⁴⁸ However, the case series of patients treated with voriconazole strongly support the notion that it is at least as effective as amphotericin B, and given its better tolerability, voriconazole may be a superior choice.³⁸ The first dedicated guidelines for hyalohyphomycosis give voriconazole a preferred treatment recommendation over lipid formulation amphotericin B.⁷³

Neutropenia is a prime risk factor for disseminated infection, and without the recovery of neutrophils, *Fusarium* infection is fatal.^{50,55} A large clinical review, which included 43 cases of invasive fusariosis at one center and 54 cases from the literature, reported a response to therapy of 30% and 48%, respectively. Cure was observed only in those patients showing resolution of myelosuppression.⁷ This is further emphasized by the fact that the only pediatric patient who survived as reported in the Schwartz case series was a girl whose neutropenia resolved.⁶⁶ Attention to immune reconstitution is critical; granulocyte

transfusions and the administration of colony-stimulating growth factors should be considered in all patients who are persistently neutropenic. Another review of fusariosis that was diagnosed among hematopoietic stem cell transplant recipients in nine centers in the United States and Brazil found that the survival rate after diagnosis was only 13%, with a median duration of 13 days.⁵⁵ The mortality rates from the pediatric series and the outbreak were 80% and 50%, respectively.^{66,77}

In summary, invasive fusariosis can be extremely difficult to diagnose and treat. In the immunocompromised patient, the clinical presentation often mimics invasive aspergillosis, but it has some unique features. Because standard doses of amphotericin B do not appear to be consistently effective, voriconazole has emerged as an attractive option for the treatment of fusariosis. Similar to invasive aspergillosis, the attention to the recovery of neutrophils is paramount, and control of the underlying disease is essential to a favorable outcome. Surgery may decrease the fungal burden and may provide time for the recovery of immune function.⁴⁰ Because of the ability of *Fusarium* organisms to attach to and to degrade plastics, removal of infected catheters and prosthetic devices is, as always, strongly recommended.

INFECTIONS CAUSED BY SCEDOSPORIUM SPECIES

Microbiology and Pathogenesis

Scedosporium is a taxonomically complex genus, of which the three most medically significant species are *Scedosporium prolificans*, *Scedosporium auranticum*, and *Scedosporium apiospermum*.^{16,31} Until recently, the anamorph (asexual stage) and teleomorph (sexual stage) forms of these fungi bore different names. For example, *S. apiospermum* is the anamorph, or asexual stage, of *Pseudallescheria boydii*. This dual naming system arose because the majority of fungi were initially identified based on their microscopic morphology, which is a function of the stage of the organism. With the advent of genetic analyses of the medically important fungi, the dual naming system became unnecessary. A series of nomenclature symposia were held to develop guidelines for a “one fungus, one name” system.⁶³ Currently, fungal nomenclature remains in transition, but the *Scedosporium* genus name is preferred for most of the organisms in this family. The taxonomy of *S. prolificans* remains a debate; this organism is also referred to by the synonymous names *Lomentospora prolificans* and *Lomentospora auranticum*. Some authors have begun to refer to all or some of this group of pathogens as the *Scedosporium/Lomentospora* complex, a designation that may serve to decrease nomenclature confusion.^{14,81} However, care must be taken when grouping these organisms because the *Scedosporium* species differ significantly in their antifungal susceptibility.³²

Scedosporium species are ubiquitous fungi recovered worldwide from polluted water, soil, and poultry and cattle manure.^{16,24,28,31,42,64,71,79} This genus has morphologic characteristics of both hyaline and dematiaceous molds.¹⁶ *S. prolificans* is a relatively new species of mold that was first described in 1984 after being isolated from a deep, subcutaneous lesion in the right foot of a 6-year-old boy¹⁶; it was initially named *Scedosporium inflatum*.^{11,28,64} More recently, human infections involving a third species, *Scedosporium auranticum*, have been described in a large population-based survey of *Scedosporium* infections in Australia.²⁴

S. apiospermum appears to be more prevalent in temperate climates compared with tropical regions.¹⁶ *S. prolificans* has mainly been isolated in the Iberian peninsula, Australia, and in some areas of the United States. In the United States, for example, *S. prolificans*-associated bone and joint infections appear to be more common in the southern states and in California.²⁶ *S. prolificans* was also found to be the most abundant pathogen in the soils of potted plants in hospitals.⁶⁹

Like other pathogenic molds, *Scedosporium* species cause disease in both immunocompetent and immunocompromised people, with localized infections most common in immunocompetent patients and disseminated infections almost exclusively limited to immunocompromised patients.¹⁶ The first case of disseminated *S. prolificans* was reported in 1991, and since that time, *Scedosporium* species have emerged as the fourth most common cause of invasive mold infections in transplant recipients after *Aspergillus*, *Mucorales*, and *Fusarium*.^{42,58} The mortality rates associated with disseminated *Scedosporium* infections

in immunocompromised patients are extremely high, ranging between 58% and 100% in reported case series.^{4,25,33,41,57-59}

The respiratory tract appears to be the portal of entry for disseminated infection in most cases, although the organism can also invade through ulcerative lesions in the gastrointestinal tract, through surgical wounds, or by inoculation from trauma.¹⁶ In localized infection, the most common mechanism seems to be direct inoculation of wounds by organisms in the environment.^{16,64} Germination into hyphae can result in hematogenous dissemination to other organs, particularly the kidneys, lungs, and brain. In the tissue, *Scedosporium* species form slender, septate hyphae with parallel cell walls that cannot reliably be distinguished from other molds, such as *Aspergillus* or *Fusarium* species, unless conidia are present.^{16,39,42}

Risk Factors and Clinical Syndromes

In immunocompetent patients, *S. boydii* is an important cause of mycetoma, a clinical syndrome characterized by infection of soft and connective tissue, joints, and bone by soil-borne fungi.⁴⁴ *S. boydii* has been estimated to cause approximately 10% of mycetoma worldwide.¹⁶ Case series in the United States and Brazil found that *S. boydii* is the most common cause of fungal mycetoma in these regions.^{22,62} Mycetoma displays a characteristic triad of symptoms: tumefaction or edematous tissue; draining sinus track formation; and presence of “grains” (balls of fungal hyphae) in pus.¹⁶ Although localized nonmycetomatous infections involving a wide range of anatomic sites in immunocompetent patients have been reported (Fig. 207.3), they are uncommon.¹⁶

An important clinical manifestation of *S. boydii* disease in immunocompetent patients is its association with sinopulmonary and central nervous system infection of victims of near-drowning incidents in polluted waters.^{9,16} The syndrome affects previously healthy individuals and generally is manifested within days to weeks of the incident, although presentation has been delayed up to nearly 5 months.¹⁶ Dissemination from the lungs to a range of anatomic sites has been reported, but the syndrome is most commonly characterized by the formation of brain abscesses.^{9,19} Although *S. boydii* is the most common mold associated with near-drowning-related infections, *Aspergillus* can also cause a similar syndrome³³; in contrast, *S. prolificans* has not been associated with near-drowning.^{16,35} Unfortunately, near-drowning-associated *S. boydii* infections carry a very poor prognosis, with mortality rates higher than 70%.¹⁶

Consistent with the respiratory tract being the most common portal of entry, *Scedosporium* species also appear to be transient colonizers of the sinopulmonary tract. A model for the host-pathogen interaction in pulmonary scedosporiosis was proposed by Cortez and associates, in which transient colonization occurs that in the setting of a normal respiratory tract is clinically insignificant.¹⁶ If the pulmonary tract has been altered by the presence of a fixed cavity, damage due to tuberculosis, or cystic fibrosis, persistent colonization can result.⁶ The first report of

this occurrence was in 1955 and involved a patient with a previous pyogenic abscess that was subsequently colonized by *S. boydii*.¹⁷ *S. apiospermum* appears to be a relatively common component of respiratory cultures isolated from patients with cystic fibrosis.^{15,81} Although a case report has described the possible cerebral dissemination of *S. apiospermum* in a patient with cystic fibrosis, the clinical significance of this colonization is not entirely clear.^{61,62} As with *Aspergillus*, persistent colonization of dysfunctional airways with *Scedosporium* species could trigger a syndrome similar to allergic bronchopulmonary aspergillosis; in fact, one multivariate analysis found that patients with cystic fibrosis who are colonized with *S. apiospermum* may have a higher risk for allergic bronchopulmonary disease (odds ratio, 13) than those colonized with *Aspergillus fumigatus* (odds ratio, 1.6).⁶⁰ However, the presence of molds such as *Scedosporium* species may be more relevant as more cystic fibrosis patients undergo lung transplantation, as illustrated by a case report describing the death of such a patient from disseminated *S. apiospermum* infection after double-lung transplantation.⁷⁰ This report emphasizes the notion that colonization of the airway can lead to dissemination when the immune status of the patient is altered.

The role of *Scedosporium* species in mold infections of immunocompromised patients has become more apparent as an increasing number of case series and large multicenter surveillance data have become available.^{4,16,24-26,31,33,57,58,67,79} *Scedosporium* is among the four most commonly isolated molds associated with invasive disease in immunocompromised patients. The rate of disseminated disease in one study was 69% for hematopoietic stem cell transplant recipients and 53% for solid-organ transplant recipients.²⁵ Risk factors and clinical manifestations parallel those caused by other filamentous molds, such as *Aspergillus* and *Fusarium* species.^{4,16,24-26,33,57,58,67,79} Prognosis is similarly poor; for example, a large multicenter case series of infections involving transplant recipients found that the overall mortality rate was 58%.²⁵

In general, although *Scedosporium* infection is often clinically and radiographically indistinguishable from other filamentous fungi infections in neutropenic patients, several unique, salient features are present that reflect a large amount of fungal replication in vivo. These include a high incidence of positive blood cultures, characteristic although not pathognomonic erythematous cutaneous lesions, frequent hematogenous spread to the central nervous system, and a high incidence of visual complaints because of endophthalmitis.^{4,16,24-26,33,41,57-59,67,79}

Diagnosis and Therapy

Histologic findings are insufficient to distinguish *Scedosporium* from other filamentous fungi, such as the *Aspergillus* species. However, scedosporiosis is frequently characterized by a high frequency of positive blood cultures. In fact, from 1990 to 1999, *S. prolificans* was the most common filamentous fungus isolated from blood culture at one hospital in Spain.²⁶ In another report, 12 of 16 patients with *Scedosporium* infections had growth in blood culture, four of 16 had growth in respiratory tract specimens, and three of 16 had growth in skin biopsy specimens.⁴ No specific studies evaluating β -glucan or galactomannan assays in the setting of proven *Scedosporium* infections have been reported, so the utility of these methods in detecting this species of mold is unclear.

Scedosporium species have low in vitro susceptibility to currently available antifungal drugs, a fact that certainly contributes to the dismal outcomes associated with these infections. The excellent review by Cortez and associates presented a large set of susceptibility data from a variety of isolates.¹⁶ In general, *S. apiospermum* appears more susceptible than *S. prolificans*; the median MIC among *S. prolificans* isolates is above 8 $\mu\text{g/mL}$ for most antifungals; of these, voriconazole is the most active agent. The agent most active against *S. apiospermum* is also voriconazole (median MIC₅₀ of 0.25 $\mu\text{g/mL}$), whereas amphotericin B has poor activity with an MIC₅₀ of 4 $\mu\text{g/mL}$.¹⁶ As with other molds, a number of studies have examined the activity of combinations of antifungal drugs, but none yielded particularly encouraging results.³⁸ The in vitro activity of the newly approved antifungal drug isavuconazole, as well as several azoles currently under development (albaconazole¹⁰ and ravuconazole) against *Scedosporium* species, has been reported.^{11,49} Of these agents, albaconazole is the most active, with geometric mean MICs toward *S. prolificans* and *S. apiospermum* of 0.35 $\mu\text{g/mL}$ and 1.0 $\mu\text{g/mL}$, respectively.¹¹ Encouragingly, albaconazole has been shown to have efficacy

FIG. 207.3 Pathology specimen from a patient with lumbar vertebral *Scedosporium apiospermum* infection. (Courtesy Wiley Schell, Duke University.)

superior to that of amphotericin B in a rabbit model of disseminated *S. proliferans* infection.¹⁰

A case series describing the treatment of scedosporiosis with voriconazole collated from the global voriconazole clinical trials database suggested that voriconazole has promising activity against both *S. apiospermum* and *S. proliferans*.⁷⁵ In this uncontrolled observational series, an overall response to therapy rate was 57%, and the overall mortality rate was 40%. Although it is difficult to make conclusions from this study, these rates are much better than those reported in previous case series.^{4,16,24-26,33,41,57-59,79} This case series also demonstrated that the difference in in vitro susceptibility of *S. apiospermum* and *S. proliferans* to voriconazole is clinically relevant; patients with *S. apiospermum* had higher survival rates than those with *S. proliferans*.

Because of the resistance of this fungus to antifungal drugs, immune function and surgical intervention play critical roles. The prognosis is particularly grim for patients with persistent neutropenia. For example, a case series of 16 patients with *S. proliferans* infections revealed that all patients who failed to recover neutrophils died.⁴ Anecdotal reports of success have been noted with the adjunctive use of granulocyte colony-stimulating factor and interferon- γ .^{8,27} These immunomodulation-based approaches are similar to those applied to other mold infections, but to date, none has progressed to the state at which it can be routinely recommended.² Surgical resection, combined with systemic antifungal therapy, should be pursued when feasible and was reported to be successful for a near-drowning victim.¹²

In summary, *Scedosporium* infections are difficult to treat and frequently occur in the immunocompromised host. The standard of care for localized infections in an immunocompetent host is surgical excision whenever possible, particularly because these organisms are highly resistant to antifungal therapy. In the immunocompromised host, in whom disseminated disease renders this approach useless, *Scedosporium* infections are generally rapidly fatal unless immune reconstitution occurs. Voriconazole appears to be the most active antifungal drug in this setting and should be considered the agent of choice. The current treatment guidelines on *Scedosporium* infections stress that there are not sufficient data to recommend specific therapies.^{5,47,73} Nevertheless, given the dismal prognosis of the disease, treatment guidelines moderately consider combination therapy with voriconazole and terbinafine, based on in vitro data and case reports of patients who had good outcomes while on this regimen. It remains to be seen whether or not such combination therapy has a significant clinical impact on *Scedosporium* disease.

Miscellaneous Mycoses

William J. Steinbach

The landscape of medical mycology is changing. Less common fungi that were once innocent or only contaminants are now emerging to lead to lethal disseminated disease in immunocompromised patients. While we are only beginning to learn about the full implications of some of these fungi, there is also the realization that nearly all of the

current therapeutic evaluations in these emerging pathogens are in vitro analyses with limited case report clinical experience. Every miscellaneous mycosis and fungal opportunist cannot be listed, and the field of taxonomy is dynamic with genera always shifting. The field is filled with continued reports of previously nonpathogenic fungi now infecting

severely immunocompromised patients. This chapter will highlight the most relevant miscellaneous fungi causing disease. Often these diseases can be classified as infection through trauma or inoculation, such as keratitis, mycetoma, or soft tissue infection, or as more invasive disease such as sinusitis, pneumonia, cerebral abscess, or disseminated infection.

YEASTS

Malassezia Species

There are 14 *Malassezia* species that have been isolated from normal and diseased human and animal skin, and *Malassezia furfur* is the most common species. Most microbiologists identify *Malassezia* as the “spaghetti and meatball” yeast that causes the prototypical recurrent skin disease tinea versicolor (also known as pityriasis versicolor), characterized by hypopigmented or hyperpigmented plaques covered in scales and generally distributed over the back, chest, and neck. Evidence also suggests that seborrheic dermatitis, a frequently relapsing skin disorder characterized by greasy, scaly, reddish patches, results from a nonspecific immune response to *Malassezia* yeasts; dandruff is linked to this yeast, and research continues on the role of this yeast in atopic eczema and psoriasis. *Malassezia* is also responsible for folliculitis in patients with underlying immunosuppression (including diabetes mellitus, transplantation, and malignancy) and intravascular catheter-related sepsis in immunocompromised patients, particularly neonates, receiving parenteral fat emulsions for nutrition.

Most invasive disease is caused by either *M. furfur* or *M. pachydermatis*. *M. furfur* is a lipophilic yeast that lacks the ability to synthesize long-chain fatty acids and requires an exogenous supply of lipids for growth, growing in culture only if C12 through C24 fatty acids are added to the medium. Most of the lipids in parenteral intralipid formulations are C16 and C18 fatty acids, chiefly linoleic acid, and oleic acid.⁵¹ This absolute requirement for long-chain fatty acids leads to specific procedures required for isolation and identification. Although *M. furfur* is obligatory lipophilic, the other major species, *M. pachydermatis*, does not require lipids for growth and is the only of the 14 *Malassezia* species that is not dependent on lipid for growth.⁵ *M. pachydermatis* is a zoophilic yeast associated with otitis externa and seborrheic dermatitis in dogs and is only occasionally isolated from human skin, but it has been implicated in invasive neonatal infection.⁷⁷ One outbreak of *M. pachydermatis* was associated with the colonized dogs of health care workers.⁹

The first invasive disease reported with *Malassezia* species was in a patient with chronic renal failure treated with peritoneal dialysis who had repeated episodes of “sterile” peritonitis, with high levels of cholesterol and triglyceride found in the peritoneal fluid after meals, thought to have originated from the small intestinal lymphatics. The yeast did not grow in culture until the agar was overlaid with olive oil.⁸⁴ Neonatal systemic *Malassezia* disease was first reported in 1981 in a 740-gram premature infant on long-term intralipid therapy through an indwelling central venous catheter.⁶⁰

Lipophilic *Malassezia* species infections (such as *M. furfur*) can be divided in two major groups: the first comprising children and adults with various forms of immunosuppression, and the second involving infants on parenteral nutrition. Most published case reports and mini-epidemics have involved infants, children, and adults with profound immunosuppression, serious concurrent health problems, and the infusion of total parenteral nutrition with lipid supplementation through central vascular catheters.²⁵ There have been numerous outbreaks in neonates involving *M. furfur*, and fewer outbreaks involving *M. pachydermatis*. A review of 55 neonates infected with *Malassezia* species found that prematurity was the most common underlying condition, followed by short-gut syndrome, but that all infected infants were receiving intralipid supplementation.⁴²

A study of the prevalence of *M. furfur* skin colonization of infants hospitalized in the intensive care unit found that of the 361 infants studied over 1 year, 133 (36.8%) had at least one positive culture for *M. furfur*. Colonized infants, compared with noncolonized infants, had younger mean gestational age, lower mean birth weight, a longer stay in the hospital, and more mean days’ use of an incubator, lamb’s wool, paper tape, and Op-Site tape, suggesting that hospitalization in an

intensive care unit often leads to *M. furfur* colonization.⁵⁸ Another study reported isolation of *M. furfur* in 41% of critically ill newborns in the neonatal intensive care unit (NICU), whereas only 10% of hospitalized newborns in nonintensive care settings were colonized.⁷ Another study reported colonization in 28% of infants in an NICU in the first week of life, but this increased to 84% in older infants.⁶

The use of intravenous fat emulsions appears to alter the microenvironment of the catheter and allows colonization and subsequent infection. Dissemination of the organism appears to be limited to the lungs, which at autopsy show lipid deposits in the arterial walls. Because of the serious underlying diseases of patients with *M. furfur* catheter sepsis, it is difficult to determine the exact role of the organism in the overall status of the patients.⁴¹ In an effort to determine whether intralipid contamination was the source of these outbreaks, an experimental study found that six blood culture isolates of *M. furfur* from infected patients grew well in both 10% and 20% parenteral fat emulsions at 35°C for 6 days. Room-temperature growth was much slower, but there was no loss of viability. The authors concluded that intralipid solution provided more optimal supplementation than vegetable oils.⁵⁷

Clinical signs and symptoms of *Malassezia* fungemia and sepsis are nonspecific, including fever, respiratory distress, lethargy, hepatomegaly, splenomegaly, and others.⁷⁷ A review of 16 infants infected with *M. furfur* revealed that most presented with classical signs of sepsis, including apnea and bradycardia, and nine had radiographic evidence of interstitial pneumonitis to accompany worsening pulmonary status. Abnormal laboratory tests included leukocytosis, elevated neutrophil band counts, and thrombocytopenia. Blood cultures were most commonly positive from the central catheter, with few peripheral (noncatheter) blood cultures positive and few organisms found on those positive cultures.⁴¹

Clinicians must maintain a high index of suspicion of *M. furfur* catheter sepsis in the appropriate clinical setting (generally central venous catheter and intralipids in a premature infant or immunocompromised patient), and laboratory investigators must be prepared to provide appropriate diagnostic methods.⁴¹ Culture of biologic fluids and biopsy specimens in selective medium, as well as an increased incubation time (10–15 days), would increase the rate of isolation of lipophilic *Malassezia* species. The blood of infants receiving lipid emulsions probably contains sufficient lipid to support initial growth of the organism, but would not be sufficient for routine identification. On subculturing, a few drops of olive oil placed on the agar surface will help in isolation.⁴¹ Therefore the frequency of infection may actually be much higher than previously reported because routine blood cultures will not detect the fungus easily. Unfortunately, *Malassezia* polymerase chain reaction (PCR) testing appears not yet ready for general use.⁷⁷

The diagnosis should not be overlooked when evaluating symptomatic, low-birth-weight, premature infants receiving total parenteral nutrition with lipid supplementation because simple removal of the catheter after the identification of the causative agent can lead to clinical improvement. In fungemia, prompt removal of the catheter, along with temporary discontinuation of the parental intralipid nutrition, is the key to therapy for *M. furfur* catheter sepsis. Most treatments in the literature focus on topical or systemic agents for the minor skin infection and not on disseminated disease.

In vitro antifungal susceptibility testing against *Malassezia* has not been standardized, and significant variation has been reported. One report of 95 *Malassezia* spp. isolates (including 74 *M. furfur* strains) revealed excellent antifungal activity with itraconazole, voriconazole, and ketoconazole, and limited activity with fluconazole.⁴⁷ There is a poor response to amphotericin B,⁴⁶ supported by the in vitro high minimum inhibitory concentration (MIC) values of this agent,⁴¹ which is in contrast to European guidelines that suggest amphotericin B.⁵ All reported studies show that the echinocandins and flucytosine have no appreciable activity against *Malassezia*, and therefore these drug classes are not recommended.⁵ Catheter removal or discontinuance of the fat emulsion therapy is required, and antifungal therapy without either of these two steps has not been shown to be efficacious.

Trichosporon Species

Fungemia caused by *Trichosporon* species is increasing in patients with hematologic malignancies and neutropenia, and has been reported as

the second most common yeast infection in cancer patients after *Candida* species.³⁶ One study showed that 10% of all fungemias at one institution were caused by *Trichosporon* spp.³⁶ *Trichosporon* spp. are able to colonize and proliferate in different parts of human body, including the gastrointestinal system, respiratory tract, skin, and vagina. More than 10% of people have been shown to be colonized by *Trichosporon* species on their normal perigenital skin (scrotal, perianal, and inguinal sites of the body).¹² The opportunistic *Trichosporon* spp. are therefore part of the cutaneous fungal microbiota in humans, and this cutaneous position may be one of the routes through which deep-seated trichosporonosis is acquired. *Trichosporon* spp. may cause deep-seated, mucosa-associated, or superficial infections, with invasive trichosporonosis documented in patients with hematologic malignancies and other immunosuppressive states, whereas superficial infections and allergic pneumonia are found predominantly in immunocompetent hosts.¹²

The taxonomy of *Trichosporon* has been revised several times and now includes 50 species. Most frequently reported species are *T. asahii* (formerly *T. beigeli* and *T. cutaneum*), *T. pullulans*, and *T. capitatum* (formerly *Blastoschizomyces capitatus*).⁴⁸ Culture identification of *Trichosporon* spp. may be difficult because it is often morphologically confused with *Candida* spp., which is worrisome because *Trichosporon* has decreased susceptibility to amphotericin B and is intrinsically resistant to echinocandins.

The clinical presentation of superficial *Trichosporon* infection in humans is often benign superficial lesions of hair, called white piedra, characterized by the presence of irregular nodules on the affected hair. These nodules are loosely attached to the hair shaft, have a soft texture, and may be white or light brown. White piedra is a disease affecting children and adults from areas with tropical and temperate climates, and most cases have been reported in children and young adults, particularly females who frequently use headbands.¹²

The first case of invasive trichosporonosis was described in 1970.⁸⁶ Clinically, the genus often causes catheter-related fungemia, but there are reports of endocarditis,¹⁰ peritonitis,³⁹ meningitis,² and pneumonitis.⁷⁰ Infections with invasive *Trichosporon* spp. are usually associated with central venous catheters, bladder catheters, and peritoneal catheter-related devices. The ability to form biofilms on implanted devices aids in the development of invasive trichosporonosis because it can promote escape from antifungals and host immune responses. Similar to biofilms of *Candida* spp., *T. asahii* cells are able to rapidly adhere to polystyrene after a 30-minute incubation.¹⁵

Trichosporon was the third most commonly isolated (10.7%) non-*Candida* yeast from one global antifungal surveillance program and was the second most common cause of yeast fungemia (after *Candida*) in patients with hematologic malignancy.⁴⁶ A multicenter retrospective Italian study was conducted to characterize cases of proven or probable invasive trichosporonosis diagnosed over the past 20 years in patients with hematologic diseases. Of 17 cases classified as *Trichosporon* spp. infections, acute myeloid leukemia accounted for 65.4% of the cases, leading to an incidence of 0.4% of *Trichosporon* spp. in acute leukemia patients, including 76.9% of cases with a positive blood culture. Pulmonary involvement was documented in 26.9% of cases, and death was reported for 64.7% of *Trichosporon* spp. infections. A literature review on 287 published trichosporonosis cases with any underlying disease revealed that *Trichosporon* spp. infections are seen with similar frequencies on all continents. Most published *Trichosporon* spp. infections occurred in patients with hematologic diseases (62.8%), with more than half suffering from acute leukemia (68% of all patients with *Trichosporon* spp.). Crude mortality rates were 77% for *Trichosporon* spp.²⁸

A worldwide review of 185 cases from 1975 to 2014³⁷ found that most patients had a history of hematologic malignancy (especially acute leukemia), as well as neutropenia and a central venous catheter. The most commonly isolated species was *T. asahii* (75%). Antifungal therapy for this invasive yeast has gravitated since the 1970s from amphotericin B to a triazole, most commonly voriconazole, and overall positive outcomes have increased.

The only published guideline on treating trichosporonosis recommends voriconazole as the preferred agent.⁵ One study of 39 *Trichosporon* clinical isolates showed high MICs for amphotericin B, with fluconazole

and itraconazole relatively lower. Posaconazole and voriconazole appeared to be more active than amphotericin B or fluconazole and similar to itraconazole. There were also potential fungicidal effects with the triazoles.⁵³ An in vitro study with eight *Trichosporon* spp. isolates showed that voriconazole was most effective, being slightly more active than itraconazole, amphotericin B, and fluconazole.⁸⁰ Another study showed that voriconazole had excellent activity, superior to amphotericin B, itraconazole, and fluconazole.²⁰ In vitro activity against several *Trichosporon* species showed that voriconazole was far superior to amphotericin B, fluconazole, and itraconazole. Notably, *T. pullulans* was generally more resistant to antifungals, including total resistance to amphotericin B and fluconazole.⁴⁵

Trichosporon species have limited susceptibility to amphotericin B, and earlier clinical studies and animal models showed that azoles were effective therapy³ and that azoles plus polyenes were potentially additive.⁴ In one study, five of 12 reported cases occurred while the patient was receiving itraconazole prophylaxis, and 11 of the 12 patients died despite amphotericin B therapy.³⁶ The mortality rate of hematogenous trichosporonosis was higher than candidiasis in that study, confirmed by a review of the published literature since the 1990s showing that *Trichosporon* spp. mortality rates were 64% to 80%³⁶ and central venous catheters were the most frequent risk factor for fungemia. Girmenia and colleagues reported the clinical outcomes for 55 patients with hematologic diseases and disseminated trichosporonosis who were treated with amphotericin B. A clinical response to amphotericin B was documented in only 13 of 55 patients (24%) evaluated.²⁸

A head-to-head comparison of various triazole antifungals against *T. asahii* found that no agents achieved fungicidal killing by time-kill studies, and the most active agents, in order, were voriconazole, itraconazole, posaconazole, isavuconazole, and fluconazole.³¹ However, no worrisome reports have been made of pan-azole resistance in *Trichosporon*⁵² or of biofilm formation at levels similar to *Candida* species, and therefore there is no evidence of development of resistance to many antifungal agents.³³

Echinocandins alone have little to no activity against *Trichosporon* spp. and are not recommended for trichosporonosis treatment. In vitro studies against the formerly named species *T. beigeli* showed that the echinocandins caspofungin and anidulafungin had no activity.¹⁹ This inactivity was validated in further studies with micafungin⁷⁵ and anidulafungin.⁸¹ Invasive *T. beigeli* infection developed in a bone marrow transplant recipient who was receiving caspofungin prophylaxis against *Aspergillus* infection.²⁹ Indeed, breakthrough trichosporonosis in immunocompromised patients after administration of amphotericin B and echinocandins, and more rarely after the use of triazoles, has been extensively reported.¹²

Rhodotorula mucilaginosa

Rhodotorula mucilaginosa (formerly *Rhodotorula rubra*) is considered to be ubiquitous because of its worldwide distribution in terrestrial, freshwater, and marine habitats and its ability to colonize a large variety of substrates. *Rhodotorula* is naturally found in soil, water, and plants and is a constituent of the normal human respiratory, gastrointestinal, and genitourinary flora.⁶⁷ Previously this organism was only considered a harmless colonizer when isolated from healthy individuals, but it is now reported in immunocompromised patients causing fungemia, endocarditis, meningitis, and peritonitis.³⁵ This is also the fungus that is chiefly responsible for the pink ring left in toilet bowls. The genus *Rhodotorula* contains 46 species, of which *R. mucilaginosa*, *R. glutinis*, and *R. minuta* cause human disease.⁸⁷

In review of all 43 reported cases from 1960 to 2000, the most common risk factor was central venous catheter insertion. It appears that the yeast is already an inhabitant of the skin and mucosa and is introduced into the bloodstream following a disruption of normal anatomic barriers. In contrast to *Trichosporon*, mortality with *Rhodotorula* is uncommon. In a review, 10 of 36 survivors of infection were not treated with antifungals and appeared to respond to removal of the infected catheter.⁶⁷ This yeast has a strong affinity for plastic,⁷ and almost all published cases involve a catheter inserted over a long period of time. One single series reported 23 cases of fungemia; only two of the patients were neutropenic, and outcome was favorable in all using various

treatment strategies of line removal alone, removal with amphotericin B, or antifungal therapy alone.³⁵

A review of 29 cases of *Rhodotorula* fungemia in Spain found that the most common underlying hematologic disorder was acute leukemia (65.5%). *Rhodotorula mucilaginosa* was the species found more frequently (79.3%), and the most common predisposing factors were the presence of central venous catheter (100%) and neutropenia (62.1%). Most patients (81.5%) were treated with amphotericin B, and the overall mortality rate was higher (13.8%) than that described in nonhematologic patients (5.8% in solid-organ neoplasms and 9% in patients with AIDS or other chronic diseases). Patients with acute leukemia had a higher mortality rate (15.7%) than patients with non-Hodgkin lymphoma (0%).²⁷

A review of 25 Brazilian cases of *Rhodotorula* spp. isolated from blood cultures found that most patients (88%) had a central venous catheter and 40% were bone marrow transplant recipients; 80% of cases were classified as a bloodstream infection. Amphotericin B was the most common antifungal used, and the catheter was removed in 89.5% of the patients, whereas death occurred in four patients (17.4%). All strains were identified as *R. mucilaginosa*, and amphotericin B demonstrated good in vitro activity, whereas fluconazole had no activity.¹³ Because of *Rhodotorula* species resistance to fluconazole and echinocandin antifungal agents, patients receiving fluconazole and caspofungin might be susceptible to the development of breakthrough *Rhodotorula* fungemia.⁴⁰

In vitro testing of 35 clinical samples of *Rhodotorula* spp. showed low MICs against all agents tested, including amphotericin B, ketoconazole, flucytosine, and itraconazole. The azoles were generally less effective than amphotericin B, and fluconazole showed an MIC of more than 32 µg/mL against all isolates.²⁶ In vitro amphotericin B is slightly superior to voriconazole and itraconazole, with general fluconazole resistance.²⁰

Guideline-recommended therapy for *Rhodotorula* infection is amphotericin B, and *Rhodotorula* species are considered generally resistant to azoles and echinocandins but susceptible to amphotericin B and flucytosine. Removal of the central venous catheter is strongly recommended.⁵

Talaromyces (Penicillium) marneffei

Talaromyces marneffei, renamed from *Penicillium marneffei* in 2015, is the only dimorphic and human pathogenic *Talaromyces* species and is endemic in tropical Asia, especially Thailand, China, and Vietnam. It has emerged as the third most common AIDS-defining illness in parts of Southeast Asia.³² Incidence of this disease has increased markedly after the first reported natural infection in 1973 of an American minister with Hodgkin disease who resided in Southeast Asia.¹⁶ From approximately 30 cases from 1973 to 1990, this infection has risen to more than 160 reported cases by 1995.¹⁸ However, epidemiology is changing again somewhat with the increased control of HIV, so now there are a greater proportion of non-HIV-infected patient cases following newer immunosuppressive modalities such as T-lymphocyte-depleting agents, anti-CD20 monoclonal antibodies, and tyrosine kinase inhibitors.⁸

Some of the most common clinical features include fever, malaise, cough and dyspnea.⁸ In approximately 85% of cases, disseminated disease can begin as numerous papules with central necrosis and located on the face and neck (Fig. 208.1).⁸³ Lesions can also appear on the upper extremities, trunk, and lower extremities. The disease can present with nonproductive cough, generalized lymphadenopathy, fever, anemia, and weight loss.¹⁸ Approximately half of the cases involve fungemia.¹⁸

T. marneffei can mimic and often can be misdiagnosed as other infections such as tuberculosis, *Pneumocystis carinii* pneumonia, cryptococcosis, and histoplasmosis. Most patients with HIV have a low CD4⁺ count. *T. marneffei* has temperature-dependent dimorphic growth, whereby below 37°C it grows as mycelia (mold) with the formation of septate hyphae and bearing conidia, but at 37°C it grows in a yeast-like form. *T. marneffei* is the only dimorphic *Talaromyces* species, and the conidia in the environment likely enter through the respiratory tract and convert to the yeast form, in which pulmonary alveolar macrophages appear to be the primary pulmonary host defense.

An in vitro study of 30 isolates revealed susceptibility to itraconazole and ketoconazole and intermediate activity to amphotericin B and fluconazole.³² Two comparative in vitro studies showed terbinafine and

FIG. 208.1 Skin lesions from *Talaromyces marneffei*. (Courtesy S. Chiewchanvit, provided by <http://www.doctorfungus.org>.)

itraconazole with similar activity,⁴⁴ and itraconazole and voriconazole possessed identical activity.⁵⁹ In another study, posaconazole showed better in vitro activity than itraconazole and amphotericin B against four isolates.⁷⁹ Micafungin showed the best in vitro activity compared with fluconazole, itraconazole, miconazole, and amphotericin B.⁷⁸

Amphotericin B has been used as successful initial management of disseminated penicilliosis in immunocompromised patients; however, it requires prolonged intravenous therapy, and relapse is common. Amphotericin B followed by itraconazole is also effective (97.3%),⁷¹ but itraconazole takes an average of 57 days to clear fungemia.⁷² A review of 74 clinical isolates showed that itraconazole generally possessed the best in vitro activity over amphotericin B, fluconazole, and ketoconazole, and thus it is generally recommended for treatment.³²

For treatment of severe cases, initial induction treatment with amphotericin B is necessary for 2 weeks, followed by an oral azole, such as itraconazole, for the next 10 weeks.⁸² Although itraconazole is presently the azole of choice, voriconazole can also be effective for chronic suppressive therapy.

MOLDS

Phaeohyphomycosis: *Cladophialophora bantiana* and *Bipolaris* Species and Others

Phaeohyphomycosis is a heterogeneous group of fungal species commonly found in the soil, distributed worldwide, and characterized by dematiaceous (darkly pigmented brown or black) hyphal forms in tissue. This staining can help distinguish between *Aspergillus* infections, and hyphae often appear more fragmented than those seen with *Aspergillus* infections.⁸⁸ The characteristic color of the hyphae is related to the presence of melanin in the fungal cell wall, which likely plays a role in fungal pathogenesis.⁵⁰ “Phaeo” comes from the Greek meaning “dark” and has been commonly used, particularly when describing infections due to these fungi as phaeohyphomycosis. It has been suggested that the term dematiaceous is not appropriate given its etymologic derivation from the Greek “deme,” meaning bundle, although it has become fairly entrenched in medical mycologic literature. The term melanized has recently been used more frequently, given its specific meaning.⁶¹ Infections can manifest as a range of clinical entities, including localized cutaneous infection and subcutaneous nodules, mycetomas (localized infections involving the cutaneous and subcutaneous tissue, fascia, and bone, often of the lower extremities, and characterized by mycotic granules), chromoblastomycosis (sclerotic bodies in tissues usually seen in tropical regions), keratitis, pulmonary infections, localized deep infections, cerebral abscesses, disseminated infection, allergic fungal sinusitis, and allergic bronchopulmonary mycosis.

Phaeohyphomycosis has been attributed to more than 150 species of fungi, spanning several orders in the kingdom Fungi. Among the most prevalent causes of human infection are *Alternaria alternata*, *Acrophialophora fusispora*, *Aureobasidium pullulans*, *Bipolaris* spp.,

Curvularia spp. (some were previously *Bipolaris*), *Chaetomium* spp., *C. bantiana*, *Exserohilum* spp., *Fonsecaea* spp., *Hortaea werneckii*, *Neoscytalidium dimidiatum*, *Verruconis gallopava* (previously *Ochroconis gallopava*), *Phaeoacremonium* spp., *Phoma* spp., *Pyrenochaeta* spp., *Rhinocladiella* spp. *Veronaea botryosa*, *Wangiella dermatitidis* (previously *Exophiala dermatitidis*), and *Phialophora* spp.^{11,50}

Diagnosis of phaeohyphomycosis relies on pathologic examination of cultures and biopsies, often with expert gross and microscopic examination required. There are no simple serologic or antigen tests to detect these fungi in blood or tissue, and PCR is in its infancy for this group of organisms. Almost all allergic disease and eosinophilia is caused by either *Bipolaris* or *Curvularia* spp.⁸⁸

Cladophialophora bantiana is the etiology for most cases of central nervous system (CNS) phaeohyphomycosis, including patients that may have no apparent immunosuppression.¹⁷ Other common etiologies of phaeohyphomycotic brain abscess are *Ramichloridium mackenziei*, *O. gallopava*, and *W. dermatitidis*.⁶² CNS disease commonly presents with a headache and a focal neurologic deficit, frequently a hemiparesis, or seizures. *Bipolaris* spp. are the most common cause of phaeohyphomycotic sinusitis, but they may also cause pneumonia, fungemia, and disseminated infections.⁸⁵

The CDC-sponsored Transplant-Associated Infection Surveillance Network (TRANSNET) collected data on 56 patients with phaeohyphomycosis from 15 centers.⁴³ Median time to diagnosis after transplantation varied by underlying type of transplantation (hematopoietic stem cell transplantation, median of 100 days; solid organ transplantation, median of 685 days). The most frequent sites of infection were the lungs, skin, and sinuses, and the most frequently isolated pathogen was *Alternaria* species (32%), followed by *Exophiala* (11%). Overall, cutaneous disease was more common in solid-organ transplant recipients, whereas pulmonary disease was more common in hematopoietic stem cell transplant recipients. In this series, bloodstream and CNS infections were only seen in hematopoietic stem cell transplant recipients.

European guidelines highlight the sparse data on preferred therapy, including in vitro data, limited animal model studies, and expert opinion.¹¹ There are no clearly defined standard therapies, but the guideline panel generally recommended voriconazole, posaconazole, or itraconazole because those agents demonstrate the most consistent in vitro antifungal activity against this group of fungi. Specifically, voriconazole is likely the best for CNS infections because of its excellent penetration. For invasive infections, surgery is crucial to the overall treatment.

In vitro studies with *C. bantiana* show similarly low MICs for voriconazole, itraconazole, and amphotericin B.²² One study showed that posaconazole had activity slightly worse than itraconazole but much better than either anidulafungin or caspofungin.¹⁹ Another study showed that itraconazole MICs were better than those of voriconazole against seven isolates,⁵⁹ whereas in another set of experiments, voriconazole had superior in vitro activity to itraconazole and amphotericin B.³⁴

The in vitro activity of drugs against *Bipolaris* species can give mixed results. Amphotericin B possessed better activity compared with voriconazole and itraconazole against *Bipolaris hawaiiensis* and *Bipolaris spicifera*.²² However, in another study voriconazole showed the best in vitro activity compared with amphotericin B, fluconazole, and itraconazole.⁴⁵ In contrast, a study with six *Bipolaris* species isolates showed itraconazole with the best activity, followed closely by voriconazole and amphotericin B,²⁰ and another study with 43 isolates showed itraconazole had great in vitro activity.⁴⁴ In the evaluation of the echinocandins, itraconazole retained the best activity, with both voriconazole and posaconazole displaying good activity, and all were far better than caspofungin or anidulafungin.¹⁹ Comparing all available triazoles, posaconazole had the most activity, followed by itraconazole, and lastly by voriconazole.⁵⁶

Including only culture-positive cases of CNS phaeohyphomycosis, the survival rate for this infection is only 35%.¹⁷ CNS lesions may be best managed surgically, and a series of 30 cases revealed that patients with single, encapsulated lesions did much better than those with multifocal disease. However, no patient who did not undergo surgery survived. Whether patients underwent neurosurgery alone or with antifungal therapy, the most important factor for cure was resectability

FIG. 208.2 Brain computed tomography image showing six enhancing lesions at initial diagnosis.

of the lesion; antifungal therapy itself was not associated with improved survival.

CNS phaeohyphomycosis continues to have a high mortality rate without surgical resection, and this may be the case for all localized cases of phaeohyphomycosis. The extended-spectrum triazoles such as voriconazole and posaconazole show good in vitro activity against *C. bantiana*, *Bipolaris* spp., and several other dematiaceous fungi, with some positive correlating clinical experience. Although the triazoles are probably more effective, the echinocandins do have some limited activity, and these agents will likely be tried in refractory cases as combination therapy. A review of 101 cases of culture-proven CNS phaeohyphomycosis found that the most frequently isolated species was *C. bantiana*, followed by *R. mackenziei*, which is seen exclusively in patients from the Middle East (Fig. 208.2). More than one-half of the cases occurred in patients with no known underlying immunodeficiency. Mortality rates were high, and therapy, although not standardized, was most successful with the combination of amphotericin B, flucytosine, and itraconazole. Complete excision of brain lesions may provide better results than simple aspiration, underscoring that a very aggressive medical and surgical approach is needed.⁶²

Hyalohyphomycosis

In contrast to phaeohyphomycosis, hyalohyphomycosis refers to infections caused by hyaline (colorless, nonpigmented, nonmelanized) septate fungal hyphae. The major hyalohyphomycotic pathogens are *Fusarium* spp. and *Scedosporium* spp. (both covered in great detail in Chapter 207), *Paecilomyces* spp., *Trichoderma* spp., *Acremonium* spp., *Scopulariopsis* spp., and *Purpureocillium* spp.⁷⁶ These species are often misidentified as *Aspergillus* spp., but they can be differentiated by their conidia and phialide morphologies.⁵⁰ Similar to the phaeohyphomycoses, diagnosis requires culture or detailed expert microscopic examination.

Fungemia can be seen when *Fusarium* spp., *Paecilomyces* spp., and *Acremonium* spp. invade tissue, and they produce hyphae as well as adventitious structures similar to microconidia that hematogenously disseminate and are found in blood culture.³⁸ *Aspergillus* does not do this, except *A. terreus*, which can elaborate lateral conidia in vitro and in vivo.⁵⁵

Paecilomyces Species

Paecilomyces species are common soil saprophytes and can be recovered from the air because they are resistant to common methods of

sterilization.⁵⁰ The two most common species associated with clinical infection are *P. variotii* and *P. lilacinus*, but the latter is now reclassified as *Purpureocillium lilacinum*. They are often confused with the *Penicillium* species and are clinically difficult to identify because their presentation can mimic better-known fungi such as dematiaceous fungi and certain other hyalohyphomycoses.⁶⁶ They can cause keratitis, endophthalmitis, and subcutaneous infections in the healthy host. In immunocompromised patients they can manifest as cutaneous disease, catheter-related fungemia, sinusitis, and disseminated disease. Many immunocompromised patients obtain infection by integument breaks with intravascular catheters or chemotherapy.⁵⁵ In fact, contaminated skin lotion has caused a nosocomial outbreak of infection in a bone marrow transplantation unit.⁷³ Of the approximately 160 cases of invasive *Paecilomyces* spp. infection reported,⁵⁴ approximately 50% are in the form of keratitis or endophthalmitis.

Amphotericin B is very potent against *P. variotii* but has poor in vitro activity against the most common species, *P. lilacinum*. Voriconazole MICs are much lower than itraconazole against *P. lilacinum*, including superior fungicidal activity²² which was confirmed in another study, but the reverse was true for *P. variotii* with itraconazole activity better than voriconazole.⁵⁹ In a study with posaconazole, it was found to have similar activity to itraconazole and better activity than amphotericin B against *P. variotii*. Posaconazole displayed significantly better activity against *P. lilacinum* compared with itraconazole, whereas amphotericin B showed no activity against that species.⁷⁹ Comparing all triazoles, posaconazole had the most activity, followed by itraconazole, ravuconazole, and finally voriconazole.⁵⁶ Caspofungin was inactive in vitro against *P. lilacinum* but showed excellent activity against *P. variotii*.¹⁴ On the other hand, micafungin showed good in vitro activity against *P. lilacinum* and *P. variotii* and better activity than fluconazole, itraconazole, miconazole, and amphotericin B.⁷⁸

In an immunosuppressed murine model of disseminated infection with *P. lilacinum*, voriconazole significantly prolonged survival with respect to the group treated with amphotericin B, reducing the fungal load in the spleen, kidneys, and liver of infected mice. Survival of mice treated with amphotericin B did not differ from that of the control group, and amphotericin B was not able to reduce the tissue burden in any organ with respect to the control group.⁶⁵ In another murine model of paecilomycosis, posaconazole was superior to amphotericin B or liposomal amphotericin B and was the only treatment able to significantly reduce fungal loads in the spleens, kidneys, and livers of the mice infected by each of the two strains.⁶⁴

The cornerstone of therapy has been surgical resection and removal of any foreign object. In vitro data suggest that the triazoles might be effective treatment for *Paecilomyces* infection; however, large datasets of clinical experience are lacking to support the recommendation, and it remains even less clear whether the echinocandins have any place in the management of these infections.

Trichoderma longibrachiatum

Trichoderma species are an ubiquitous component of soil and play an important role decomposing plant material, with several species of the genus *Trichoderma* identified as etiologic agents of infection in immunocompromised hosts, including *T. longibrachiatum*, *T. citrinoviride*, *T. harzianum*, *T. koningii*, *T. pseudokoningii*, and *T. viride*.^{63,68} *T. longibrachiatum* causes virtually all human infections and has been reported to cause pulmonary, cerebral, soft tissue, and disseminated disease in immunocompromised patients. It has been suggested that *T. longibrachiatum* can be acquired through the gastrointestinal tract, and prolonged therapy with fluconazole and antibacterial agents may selectively favor this filamentous fungi.⁶³ Another likely source may be aerosols or contaminated water.⁵⁰ The first case of *Trichoderma* infection in an immunocompromised patient was reported in 1976, and a review lists only 10 cases reported in immunocompromised hosts.⁶³

Itraconazole displays the best in vitro activity among older antifungals.^{24,49,69,74} Other studies showed itraconazole with no activity, and amphotericin B had better activity than voriconazole.²¹ However, amphotericin B resistance is uniform in reported clinical cases. Extended-spectrum triazoles should be considered over the polyenes for treatment, but recovery from immunosuppression appears crucial to success. In

one series, voriconazole had superior in vitro antifungal activity over posaconazole and itraconazole, amphotericin B showed nearly zero antifungal activity, and the echinocandins also showed excellent antifungal activity.⁶⁸ Stool surveillance cultures for early identification of this fungus remain unproved for clinical management but may play a role with future studies.

Acremonium Species

Acremonium species are ubiquitous in the environment and common in soil, plant debris, and rotting mushrooms; *A. kiliense* (now reclassified as *Sarocladium kiliense*) is the most important among the 10 species reported as infectious etiologies in vertebrates. *Acremonium* spp. grow slowly, so culture plates need to be incubated for at least 2 weeks for detection. The immunocompetent host can form a mycetoma or develop an ocular infection after sustaining a penetrating injury.³⁰ *Acremonium* spp. can lead to a wide range of infections from keratitis to disseminated disease, with the lung and gastrointestinal tract as apparent portals of entry.⁸⁵

The first case of *Acremonium* spp. infection other than mycetoma or ocular infection was described in 1932, but most have arisen since 1985.³⁰ The largest review of 36 localized or disseminated cases showed that most disseminated cases occurred in immunocompromised patients and only approximately one-half could be cured, with complete resolution of disease dependent on neutrophil recovery.³⁰ Recognition of disseminated *Acremonium* infection is difficult because specific signs and symptoms do not exist. Patients may present with a cutaneous nodule, papular skin rash, or fungemia.

The rarity of *Acremonium* infections makes it difficult to adequately assess the best treatment regimen. Amphotericin B was previously recommended as initial therapy,²³ and despite the in vitro resistance to azole treatment, the combination of surgery and azoles has often been successful.³⁰ Voriconazole appears to have the greatest in vitro activity against *Acremonium*, and European guidelines recommend voriconazole as initial antifungal therapy.⁷⁶ Similar to other fungal pathogens, the status of the host defense system is crucial. *Acremonium* infections are still rare but deadly, and the limited amount of clinical experience makes firm recommendations difficult. The echinocandins appear to have limited activity, whereas the newer triazoles may be beneficial adjunctive therapy in concert with boosting the host immune response.

In one study, itraconazole had no activity and voriconazole had a marginally effective MIC for *A. kiliense*.⁵⁹ Another study showed voriconazole with the best in vitro activity compared with amphotericin B, fluconazole, and itraconazole for *A. alabamensis* and *A. strictum*.⁴⁵ Anidulafungin has no activity against *Acremonium* species, but posaconazole and caspofungin both possess some fungistatic activity against *A. strictum*.¹⁹ A more recent study showed that voriconazole and ravuconazole had similar activity and had superior activity to posaconazole, whereas the strains tested were resistant to amphotericin B and itraconazole.⁵⁶

Classification and Nomenclature of Human Parasites

209

Lynne S. Garcia

Although common names frequently are used to describe parasitic organisms, these names may represent different parasites in different parts of the world. To eliminate these problems, a binomial system of nomenclature in which the scientific name consists of the genus and species is used.^{1,4,5,13,17,18,22} These names generally are of Greek or Latin origin. In certain publications, the scientific name often is followed by the name of the person who originally named the parasite. The date of naming also may be provided. If the name of the individual person is in parentheses, it means that the person used a generic name no longer considered to be correct.

On the basis of life histories, morphologic characteristics, and molecular techniques, systems of classification have been developed to indicate the relationships among the various parasite species. Closely related species are placed in the same genus, related genera in the same family, related families in the same order, related orders in the same class, and related classes in the same phylum, one of the major categories in the animal kingdom. As one moves up the classification schema, each category becomes broader; however, each category still has characteristics in common.

Parasites of humans are classified in several major divisions. They include the Protozoa (amebae, flagellates, ciliates, sporozoans, and coccidia), the Fungi (microsporidia), the Platyhelminthes or flatworms (cestodes, trematodes), the Acanthocephala or thorny-headed worms, the Nematoda or roundworms, and the Arthropoda (insects, spiders, mites, ticks, and so on). Although these categories appear to be well defined, often considerable confusion occurs in attempting to classify parasitic organisms. One of the primary reasons is the lack of known specimens. Some organisms recovered from humans are very rare; difficulty thus arises in determining morphologic and physiologic variations among such groups. Type specimens must be deposited for study before a legitimate species name can be given. Even when certain parasites are numerous, they may represent strains or races of the same species with slightly different characteristics.

Generally, reproductive mechanisms are valid in determining definitions of species, but so many exceptions exist within parasite groups that taking into consideration properties such as sexual reproduction, parthenogenesis, and asexual reproduction is difficult. Other difficulties in recognition of species are the ability and the tendency of the organisms to alter their morphologic forms according to age, host, or nutrition,

changes that often result in several names given to the same organism. An additional problem involves alternation of parasitic and free-living phases in the life cycle. These organisms may be very different and difficult to recognize as belonging to the same species. Despite these difficulties, newer, more sophisticated molecular methods of grouping organisms often have confirmed taxonomic conclusions reached hundreds of years earlier by experienced taxonomists.

As investigations continue in parasitic genetics, immunology, biochemistry, and molecular studies, the species designation will be defined more clearly. Originally, these species designations were determined primarily by morphologic differences, resulting in a phenotypic approach. With the use of highly sophisticated molecular techniques, the approach will continue to be more genotypic. Benefits of these studies also include the development of highly specific and sensitive diagnostic tests and the ability to diagnose parasitic infections on the basis of molecular parameters, rather than merely phenotypic characteristics.

Although gaps in our knowledge concerning classification of all human parasites remain, the binomial system has allowed the classification of 1.5 million species of organisms in the animal kingdom such that all published information can be retrieved, regardless of the language spoken. The difficulty for the clinician arises when one considers the rapid increase in information concerning microbiology during the past few years and changing considerations such as the role of immunosuppression in the host-parasite interaction and the modified definitions of “normal flora” and “nonpathogenic” in this patient population.

The classification of parasites is presented in tabular form. Although certain designations of species may be somewhat controversial, this classification scheme is designed to provide some order and meaning to a widely divergent group of organisms. No attempt has been made to include every possible organism, and only those organisms considered clinically relevant in the context of human parasitology are included. The main groups that are presented include protozoa and fungi (Box 209.1), nematodes (roundworms; Box 209.2), cestodes (tapeworms; Box 209.3), and trematodes (flukes; Box 209.4). Some relevant information on Acanthocephala (Box 209.5) and arthropods (Tables 209.1 and 209.2) is also presented. The hope is that this information will provide some insight into the parasite groupings, thus leading to a better understanding of parasitic infections and the appropriate diagnostic and clinical approach.

Keywords

classification
human infections
parasitology

BOX 209.1 Protozoa

Amebae—Intestinal

These organisms are characterized by having pseudopods (motility) and trophozoite and cyst stages in the life cycle and include some exceptions in which a cyst form has not been identified. Amebae usually are acquired by humans through fecal-oral transmission or mouth-to-mouth contact (*Entamoeba gingivalis*).

Current Name

Entamoeba histolytica^a
Entamoeba dispar^a
Entamoeba hartmanni^b
Entamoeba coli
Entamoeba polecki
Entamoeba moshkovskii
Entamoeba bangladeshi
Entamoeba gingivalis
Endolimax nana
Iodamoeba bütschlii
Blastocystis spp.^c

Flagellates—Intestinal

These organisms move by means of flagella and are acquired by fecal-oral transmission. With exception of the genera *Trichomonas* and *Pentatrichomonas*, they have trophozoite and cyst stages in the life cycle. *Trichomonas* and *Pentatrichomonas* spp. do not have a cyst stage.

Current Name

Giardia lamblia^d
Chilomastix mesnili
Dientamoeba fragilis^e
Pentatrichomonas hominis
Trichomonas tenax
Enteromonas hominis
Retortamonas intestinalis

Ciliates—Intestinal

These organisms, which move by means of cilia, are acquired by humans through fecal-oral transmission. They have both trophozoite and cyst forms in the life cycle.

Current Name

Balantidium coli

Apicomplexa, Sporozoa (Intestinal)

These organisms are acquired by humans by ingestion of various meats or through fecal-oral transmission through contaminated food or water.

Current Name

Apicomplexa
Cryptosporidium hominis^f
Cryptosporidium parvum^g
Cryptosporidium spp.
Cyclospora cayentanensis^{23,24}
Cystoisospora (Isospora) belli
Sarcocystis hominis
Sarcocystis suihominis
Sarcocystis bovis
Sarcocystis heydorni^h

Fungi (Microsporidia⁹)—Intestinal

Enterocytozoon bienersi
Encephalitozoon (Septata) intestinalis^h

Amebae, Flagellates—Other Body Sites

The amebae are pathogenic, free-living organisms that may be associated with warm, freshwater areas. They have been found in the central nervous system, the eye, and other sites. *Trichomonas vaginalis* usually is acquired by sexual transmission. This particular flagellate is found in the genitourinary system.

Current Name

Amebae
Naegleria fowleri
Acanthamoeba spp.
Hartmannella spp.
Balamuthia mandrillaris
Sappinia diploidea

Flagellates

Trichomonas vaginalis

Apicomplexa, Sporozoa (Coccidia)—Other Body Sites

The coccidia are particularly important in the compromised patient. They also may infect many persons who have no apparent symptoms.^{11,12} On the basis of molecular studies, the microsporidia are linked more closely to the fungi and have been reclassified with those organisms. However, during this transition phase, their classification will remain with the parasites.

Current Name

Coccidia
Toxoplasma gondii

Fungi (Pneumocystis,ⁱ Microsporidia)—Other Body Sites

Microsporidia
Anncaliia (Brachiola) connori
Anncaliia (Brachiola) algerae
Anncaliia (Brachiola) vesicularum
Encephalitozoon cuniculi
Encephalitozoon hellem
Encephalitozoon intestinalis^j
Enterocytozoon bienersi^k
Microsporidium africanum^l
Microsporidium ceylonensis^l
Nosema ocularum
Pleistophora ronniae
Trachipleistophora hominis
Trachipleistophora anthropophthera
Tubulinosema acridophagus
Vittaforma corneae^m

Sporozoa, Flagellates—Blood and Tissues

All these organisms are arthropod borne. The diagnosis may be somewhat more difficult to make than that of infection with the intestinal protozoa, particularly if automated blood differential systems are used. The *Leishmania* genus has undergone extensive revisions in classification. However, from a clinical perspective, recovery and identification of the organisms still are related to body site. Recovery

BOX 209.1 Protozoa—cont'd

of the organisms is limited to the site of the lesion in infections other than those caused by the *Leishmania donovani* complex (visceral leishmaniasis).

Current Name**Apicomplexa, Sporozoa (Malaria, Babesiosis)****Malaria**

Plasmodium vivax
Plasmodium ovale
Plasmodium malariae
Plasmodium falciparum
*Plasmodium knowlesi*⁷

Babesiosis⁹

Babesia microti
Babesia divergens
Babesia duncani
Babesia spp.

Flagellates (Leishmaniasis, Trypanosomiasis)**Leishmaniasis**

Leishmania tropica complex (cutaneous leishmaniasis)
Leishmania infantum complex (cutaneous leishmaniasis)
Leishmania major complex (cutaneous leishmaniasis)
Leishmania mexicana complex (cutaneous leishmaniasis)
Leishmania braziliensis complex (mucocutaneous leishmaniasis)
Leishmania donovani complex (visceral leishmaniasis)

Trypanosomiasis

Trypanosoma brucei gambiense (West African trypanosomiasis)
Trypanosoma brucei rhodesiense (East African trypanosomiasis)
Trypanosoma cruzi (American trypanosomiasis)
Trypanosoma rangeli

⁹*E. histolytica* is being used to designate the true pathogen, whereas *Entamoeba dispar* is being used to designate a nonpathogen. Unless trophozoites containing ingested red blood cells (*E. histolytica*) are seen during microscopic examination, or a specific immunoassay for the pathogen (*E. histolytica*) is used, the two organisms cannot be differentiated on the basis of morphology seen in permanent stained smears of fecal specimens and will be reported as *E. histolytica/E. dispar*. Some laboratories are now using the term *E. histolytica/E. dispar* group; other organisms share a typical morphology (*E. moshkovskii*, *E. bangladeshii*). Fecal immunoassays for antigen detection are available commercially for differentiating *E. histolytica* from *E. dispar* and for detecting the *E. histolytica/E. dispar* group.¹² Because the differences in pathogenicity are genetic and not just phenotypic, the decision to treat is one that must be determined by the physician. The finding of organisms of the *E. histolytica/E. dispar* group in patients' specimens must continue to be reported to state and county departments of public health (follow your particular state reporting regulations).

¹⁰*E. hartmanni* is nonpathogenic and is totally different from *E. histolytica*. "Small race *E. histolytica*" is incorrect and should not be used at any time to designate *E. hartmanni*.

¹¹Currently, this organism is classified as an anaerobic, single-celled stramenopile (brown algae; Kingdom Chromista, class Blastocystea).²⁷ *Blastocystis* is comprised of a number of subtypes, approximately half of which are pathogenic and half are nonpathogenic. However, from organism morphology seen microscopically, these subtypes cannot be differentiated. Therefore the diagnosis of this organism should be considered potentially pathogenic for the patient.

¹²Although some investigators have changed the species designation for the genus *Giardia* to *G. duodenalis* or *G. intestinalis*, no consensus exists. Therefore, for this listing, we retain the name *G. lamblia*. However, molecular and epidemiologic evidence suggests that at least two assemblages of *Giardia* infect humans, one of which is *G. duodenalis* and the other, possibly a new species, *G. enterica*.²¹

¹³The cyst stage has been confirmed in *D. fragilis*.²⁵ On the basis of electron microscopy studies, *D. fragilis* has been reclassified as an ameboflagellate rather than an ameba and is closely related to *Histomonas* and *Trichomonas* spp. However, it is normally referred to as a flagellate.

¹⁴*C. parvum* infects cattle, sheep, goats, and humans as primary hosts, but *C. hominis* infects only humans and primates.

¹⁵The microsporidia are now thought to be more closely related to fungi than to protozoa; however, clinical parasitologists have been reluctant to part with this group, whereas mycologists have been equally reluctant to accept it. Consequently, the microsporidia are retained within this list for parasites, although they are classified within the Fungi.^{3,16,28,29}

¹⁶Formerly called *Septata intestinalis*.^{15,20}

¹⁷*Pneumocystis carinii* has been reclassified with the fungi and renamed *Pneumocystis jirovecii*.^{10,18,26} Consequently, it will be removed from future parasite listings. An unusual group of spore-forming fungi, and the earliest-diverging clade of sequenced fungi,³ microsporidia lack mitochondria or mitochondrial remnants and are obligate intracellular eukaryotic unicellular parasites. Microsporidia can rapidly extrude their polar tubes, which penetrate the host plasma membrane. The sporoplasm is transferred into the host cells, where the spores develop and complete their life cycles. At this point parasitologists are reluctant to relinquish these organisms, whereas mycologists are reluctant to accept them; consequently they are included in this parasite classification list.

¹⁸Formerly called *Septata intestinalis*.

¹⁹*E. bienersi* has been recovered from sites other than the intestinal tract.

²⁰This designation is now written as a true genus, but it remains a "catch-all" for those organisms that have not been (or may never be) identified as belonging to the true genus or species levels.

²¹Formerly called *Nosema corneum*.

²²*P. knowlesi*, a malaria parasite of macaque monkeys in Southeast Asia that is now established as a naturally transmitted parasite of humans in Malaysia and other parts of Southeast Asia, has been responsible for a number of deaths.^{6,19} Thus, five species of malaria pathogens now that infect humans.

²³Molecular studies confirm that humans can also harbor several *Babesia* parasites that have not yet been identified.¹⁴

BOX 209.2 Nematodes

Intestinal

These organisms normally are acquired by ingestion of eggs or penetration of the skin by larval forms from the soil.

Current Name

Ascaris lumbricoides
Enterobius vermicularis (pinworm)
Ancylostoma duodenale (Old World hookworm)
Necator americanus (New World hookworm)
Strongyloides stercoralis

Strongyloides fuelleborni

Trichostrongylus spp.

Trichuris trichiura (whipworm)

Capillaria philippinensis

Oesophagostomum spp. (*O. bifurcum* most common in humans—West Africa)

Ternidens diminutus (as high as 80% in Zimbabwe)

Tissue

For the most part, these organisms rarely are seen within the United States; however, the first three are more important.

Continued

BOX 209.2 Nematodes—cont'd

Current Name*Trichinella spiralis**Trichinella* spp.*Toxocara canis* or *T. cati* (visceral or ocular larva migrans)*Ancylostoma braziliense* or *A. caninum* (cutaneous larva migrans)*Ancylostoma ceylanicum*²*Baylisascaris procyonis* (severe systemic visceral larva migrans, neural larva migrans)*Dracunculus medinensis**Angiostrongylus cantonensis**Angiostrongylus costaricensis**Gnathostoma spinigerum**Gnathostoma* spp.

Anisakiasis (larvae from salt-water fish)

Anisakis spp.*Phocanema* spp.*Contracaecum* spp.*Pseudoterranova* spp.*Hysterothylacium* spp.*Porrocaecum* spp.*Capillaria hepatica**Diocotophyma renale**Thelazia* spp.**Filarial Worms—Blood, Other Body Fluids, Skin**

These organisms also are arthropod borne. The adult worms tend to live in the lymphatic tissues. The diagnosis is made on the basis of the recovery and identification of the larval worms (microfilariae) in the blood, other body fluids, or skin. Elephantiasis may be associated with some of the organisms listed.

Current Name*Wuchereria bancrofti**Brugia malayi**Brugia timori**Loa loa**Onchocerca volvulus**Mansonella ozzardi**Mansonella streptocerca**Mansonella perstans**Dirofilaria immitis* ("coin" lesion in the lung) (dog heartworm)*Dirofilaria* spp. (may be found in subcutaneous nodules)

BOX 209.3 Cestodes

Intestinal

The adult form of these organisms is acquired by humans through ingestion of the larval forms contained in poorly cooked or raw meats or freshwater fish. In the case of *Dipylidium caninum*, infection is acquired by the accidental ingestion of dog fleas. Both *Hymenolepis nana* and *H. diminuta* are transmitted by ingestion of certain arthropods (fleas, beetles). Also, *H. nana* can be transmitted through egg ingestion (life cycle in the human can bypass the intermediate beetle host). Humans can serve as both the intermediate and definitive hosts in *H. nana* and *Taenia solium* infections.

Current Name*Diphyllbothrium latum* (broad, fish tapeworm)*Dipylidium caninum* (dog tapeworm)*Hymenolepis (Rodentolepis) nana* (dwarf tapeworm)*Hymenolepis diminuta* (rat tapeworm)*Taenia solium* (pork tapeworm)*Taenia saginata* (beef tapeworm)*Taenia asiatica* (Taiwanese variant of *T. saginata*)**Larval Forms—Tissue**

The ingestion of certain tapeworm eggs or accidental contact with certain larval forms can lead to the diseases shown in parentheses.

Current Name*Taenia solium* (cysticercosis)*Echinococcus granulosus* (hydatid disease)*Echinococcus canadensis*⁷*Echinococcus multilocularis* (alveolar hydatid disease)*Echinococcus oligarthrus* (polycystic hydatid disease)*Multiceps multiceps* (coenurosis)*Diphyllbothrium* spp. (sparganosis)*Spirometra mansonoides* (sparganosis)

BOX 209.4 Trematodes

Intestinal

These organisms are uncommon within the United States, except for four species of *Alaria*, which are endemic within North America.

Current Name*Fasciolopsis buski* (giant intestinal fluke)*Echinostoma ilocanum**Eurytrema pancreaticum**Heterophyes heterophyes**Metagonimus yokogawai**Alaria* spp.*Fasciola hepatica* (sheep liver fluke)*Paragonimus westermani* (lung fluke)*Paragonimus kellicotti* (lung fluke endemic in the United States)*Paragonimus* spp.*Metorchis conjunctus* (North American liver fluke)**Blood**

The schistosomes are acquired by penetration of the skin by the cercarial forms that are released from freshwater snails. Although they are not endemic within the United States, occasionally patients are seen who may have these infections.

Current Name*Schistosoma mansoni**Schistosoma haematobium**Schistosoma japonicum**Schistosoma intercalatum**Schistosoma mekongi***Liver, Lung**

These organisms are not seen commonly within the United States; however, some Southeast Asian refugees do harbor some of these parasites.

Current Name*Clonorchis (Opisthorchis) sinensis* (Chinese liver fluke)*Opisthorchis viverrini*

TABLE 209.1 Human Vector-Borne Infections

Infection (Disease)	Causative Agent	Vector (Common Name)
Protozoal		
Malaria	<i>Plasmodium</i> spp.	Mosquitoes
Leishmaniasis	<i>Leishmania</i> spp.	Sandflies
Chagas disease	<i>Trypanosoma cruzi</i>	Triatomid bugs
East African trypanosomiasis	<i>Trypanosoma brucei rhodesiense</i>	Tsetse flies
West African trypanosomiasis	<i>Trypanosoma brucei gambiense</i>	Tsetse flies
Babesiosis	<i>Babesia</i> spp.	Ticks
Helminthic		
Filariasis	<i>Wuchereria bancrofti</i>	Mosquitoes
Filariasis	<i>Brugia malayi</i>	Mosquitoes
Filariasis	<i>Dirofilaria</i> spp.	Mosquitoes
Filariasis	<i>Mansonella perstans</i>	Biting midges
Filariasis	<i>Mansonella streptocerca</i>	Biting midges
Filariasis	<i>Mansonella ozzardi</i>	Biting midges
Onchocerciasis	<i>Onchocerca volvulus</i>	Black flies
Loiasis	<i>Loa loa</i>	Deer flies
Dog tapeworm infection	<i>Dipylidium caninum</i>	Dog lice and fleas, human fleas
Rat tapeworm infection	<i>Hymenolepis diminuta</i>	Rat fleas, beetles, grain beetles
Dwarf tapeworm	<i>Hymenolepis nana</i>	Grain beetles (rare)

TABLE 209.2 Medically Important Arthropods

Local or Systemic Problems	Vector (Common Name)
Skin reaction to bites	Sucking lice
	Bedbugs
	Kissing bugs
	Biting midges
	Sandflies
	Black flies
	Mosquitoes
	Deer flies
	Tsetse flies
	Soft ticks
Painful bite	Hard ticks
	Horseflies
	Fire ants
Intense itching	Centipedes
	Human itch mites
Painful sting, potential anaphylaxis	Chiggers
	Honeybees
	Bumblebees
	Wasps, hornets, yellow jackets
	Fire ants
Dermatitis, ulcerations	Scorpions
	Fleas
Nodular ulceration with subsequent secondary infection	Chigoe flea
Blistering of skin after contact with adult beetles	Blister beetles
Bite, usually painless, delayed systemic reaction	Black widow spiders
Initial blister followed by extensive necrosis and slow healing	Brown recluse spiders
	South American brown spider

BOX 209.5 Acanthocephala

The Acanthocephala or thorny-headed worms are normally parasites of fish. Although two species are found in humans, these infections tend to be somewhat rare.

Moniliformis moniliformis

Macracanthorhynchus hirudinaceus

*Macracanthorhynchus ingens*³

Diarrheal diseases continue to be major causes of morbidity and mortality in children in developing countries. In Bangladesh, 10% of children in the first year of life have amebic diarrhea, and one in 30 children dies of diarrhea or dysentery by age 5 years.⁸⁵ Amebiasis is an infection caused by the protozoan parasite *Entamoeba histolytica*. Infection occurs by ingestion of the parasite's cyst from fecally contaminated food, water, or hands. Approximately 55,500 deaths, 50 million illnesses, and 2.24 million disability-adjusted life years occur annually from amebiasis, thereby rendering it the third leading cause of death by parasitic disease in humans.^{79,85} Although amebiasis is present worldwide, it occurs most commonly in developing areas, especially Asia, sub-Saharan Africa, and Central and South America. In the United States and other developed countries, cases of amebiasis are most likely to occur in immigrants from and travelers to endemic regions, but amebiasis can affect populations of the developed world, as shown by the epidemic in Tbilisi in the Republic of Georgia that was caused by contaminated municipal water.¹³ Currently, there is no vaccine to prevent the childhood morbidity and mortality resulting from infection with *E. histolytica*.

ETIOLOGY

E. histolytica is the cause of amebiasis and was named for the pathologic evidence of "lysis" of tissues. Additional *Entamoeba* spp. that infect humans and that are identical in appearance microscopically to *E. histolytica* include the following: *E. dispar*, which is nonpathogenic; *E. moshkovskii*, which may cause diarrhea¹⁰⁴; and the more recently identified enteric parasite *E. bangladeshi*.¹⁰⁰ The first demonstration of the organism in human tissues was made by Lambi in 1859 in the postmortem examination of the colon of a child who died as a result of excessive diarrhea.^{16,81} No connection of the organism with the disease was made until 1875, when Losch,⁶³ in St. Petersburg, Russia found the organism at autopsy in the colon of a woodcutter. Losch induced diarrhea and ulcerations in a dog given feces from the patient. He did not think, however, that a connection existed between the organism and the disease. The first patient described in the United States was a physician treated by Osler⁸¹ for an amebic liver abscess in 1890. Councilman and Lafleur²⁸ described the organism and the disease in 1891.^{21,46} Further investigation of the disease was delayed until a better understanding of the life cycle of *E. histolytica* could be obtained. In more recent years, the application of modern molecular biology techniques to the study of *E. histolytica* and *E. dispar* has resulted in an explosion of information about the mechanisms of virulence, pathogenicity, and immune responses to these organisms.^{96,98}

E. histolytica is the pathogenic species, with the capacity to invade tissue and cause symptomatic disease, whereas *E. dispar* (and *E. histolytica*) is associated with the asymptomatic carrier state.^{6,32,96} More recently, a study revealed that all genotypes of *E. histolytica* are not equally capable of causing disease.⁶ Morphologically distinct members of the genus *Entamoeba*, such as *Entamoeba coli* and *Entamoeba hartmanni*, also are nonpathogenic. *Entamoeba moshkovskii*, *Dientamoeba fragilis*, and *Entamoeba polecki* have been associated with diarrhea, and *Entamoeba gingivalis* has been associated with periodontal disease.

Members of the genus *Entamoeba*, which are protozoan organisms belonging to the subphylum Sarcodina and close to *Dictyostelium discoideum* on one of the lowest branches of the eukaryotic tree, have trophozoite and cyst forms.⁴⁰ The cysts of *E. histolytica*, *E. dispar*, *E. moshkovskii*, and *E. bangladeshi* are almost spherical, surrounded by a

cell wall composed of chitin. The cysts may have one to four nuclei, although quadrinucleate cysts are most typical. This feature allows differentiation from *E. coli*, which usually has six to eight nuclei in the cysts and may have 32 nuclei.⁸² Cysts of *E. histolytica* are 5 to 20 μm in diameter (average, 12 μm) and have a greenish tint in the unstained condition.⁶⁴ Young cysts contain chromatoid bodies, which are composed of ribosome particles in crystalline arrays.¹² The cysts of *E. hartmanni* appear identical to those of *E. histolytica* except for being smaller (4–10 μm). *E. histolytica* cysts can survive for days in the dried state at 30°C or for months at 0°C to 4°C. They can be killed by temperatures greater than 50°C retained for 5 minutes.⁴⁶ They are completely resistant to the concentrations of chlorine used in water supplies but may be killed with hyperchlorination or with iodine solutions.^{64,82} They are filtered from water supplies that pass through a sand filtration phase. They resist acids well.

When these quadrinucleate cysts are ingested, they resist the acid pH of the stomach and ultimately excyst in the alkaline environment of the bowel. The process of excystation results in the release of four trophozoites that divide by binary fission to produce eight trophozoites. The usual trophozoites have a diameter of 25 μm (range, 10–60 μm).^{28,96} They have a single nucleus that is 3 to 5 μm in diameter and contains fine peripheral chromatin with a slightly eccentric karyosome. They have a granular endoplasm that typically contains vacuoles in which bacteria and debris can be seen. Some glycogen is present and can be stained with periodic acid–Schiff stain.

Although amebae were thought to lack organelles, such as mitochondria, endoplasmic reticulum, and Golgi apparatus, evidence to the contrary is coming to light. The existence of nuclear-encoded mitochondrial genes and a remnant mitochondrial organelle was reported more recently.^{65,74,111} The presence of ingested erythrocytes is a characteristic feature of *E. histolytica* but not *E. dispar*.⁹⁶ Movement is accomplished by extension of clear pseudopodia. Replication is by binary fission. These protozoa live in the colon of humans and other mammals. Trophozoites die quickly outside the body and are quite sensitive to acid. Therefore they generally are not considered to be infective.³³ When cooled (as when feces are expelled and gradually cooled from body temperature) or stimulated by as yet undefined luminal conditions, the trophozoites form cysts that can remain viable for weeks to months on excretion.⁹⁶

Trophozoites of *E. coli* are 15 to 50 μm in diameter; they have much more sluggish motility than the trophozoites of *E. histolytica*; and they have blunt pseudopodia, rather than the sharp, finger-like pseudopodia of *E. histolytica*. Trophozoites of *E. hartmanni* are 4 to 14 μm in diameter and have much less glycogen than the trophozoites of *E. histolytica*.²⁸

EPIDEMIOLOGY

Amebiasis is distributed throughout the world. The number of people infected with either *E. histolytica* or *E. dispar* per year is estimated to be 500 million. Although most people remain asymptomatic, thus perpetuating the natural cycle of the organism through fecal excretion of infective cysts, approximately 50 million people experience the severe morbidity associated with invasive disease, with an estimated 55,500 deaths annually and 2.24 million disability-adjusted life years.^{85,108} In the United States, 50% of cases of amebiasis are observed in Hispanics, Asians, and Pacific Islanders. Travelers from developing countries, malnourished persons,⁷⁶ men, and residents of institutions for the

BOX 210.1 Risk Factors for Amebiasis in the United States

Hispanic/Asian/Pacific Islanders: 50% of US cases reported to the Centers for Disease Control and Prevention

Travelers to endemic regions of the world: 0.3% incidence in one study
Institutions for intellectually disabled

Men who have sex with men

Men: 90% amebic liver abscesses found in men; rare in children

intellectually disabled are considered to be at higher risk for amebiasis (Box 210.1). In parts of Asia and Australia, *E. histolytica* is also common in men who have sex with men and can be sexually transmitted.⁴⁸ A study in Japan detected antibodies to *E. histolytica* in 21% of 1303 patients with human immunodeficiency virus infection; 88% of *E. histolytica* infections were in men who has sex with men.⁶⁷

During the 1990s, enough evidence had accumulated to support the formal separation of two morphologically identical species of ameba, the nonpathogenic *E. dispar* from the potentially pathogenic *E. histolytica*.^{1,14,31,32,39,108} Morbidity and mortality data in absolute numbers that existed before this time pertaining to cases of invasive disease were not greatly affected by this reclassification because all invasive disease was known to be caused by *E. histolytica*.¹⁰⁸ Because most prevalence and incidence data previously collected pertained to asymptomatic persons, however, and it was clear that most asymptomatic persons with cysts detected in their stool were infected with nonpathogenic *E. dispar*, the true prevalence and incidence of *E. histolytica* became a matter of speculation.¹⁰⁸

Estimates of *E. histolytica* infections have been made primarily on the basis of examinations of stool for cysts and parasites, but these tests are insensitive and cannot differentiate *E. histolytica* from morphologically identical species, such as *E. dispar* organisms that are nonpathogenic and *E. moshkovskii* and *E. bangladeshi*.^{5,23} Specific and sensitive means to detect *E. histolytica* in stool are now available and include antigen detection and polymerase chain reaction (PCR) analysis.^{1,45,60}

A prospective study of preschool children in a slum of Dhaka, Bangladesh showed *E. histolytica*-associated diarrhea in 9% and *E. histolytica*-associated dysentery in 3% of the children annually.⁴³ Not all people are equally susceptible to amebiasis; a leptin receptor polymorphism and certain human leukocyte antigen (HLA)-DR and HLA-DQ alleles are associated with resistance to infection and disease.^{24,25,80} The annual incidence of amebic liver abscess was reported to be 21 cases per 100,000 inhabitants in Hue City, Vietnam.¹⁴ Carefully conducted serologic studies in Mexico, where amebiasis is endemic, showed antibody to *E. histolytica* in 8.4% of the population.¹⁸ In the urban slum of Fortaleza, Brazil, 25% of all residents tested carried antibody to *E. histolytica*; the prevalence of antiamebic antibodies in children 6 to 14 years old was 40%.¹⁵

PATHOGENESIS AND PATHOLOGY

The cysts are transported through the digestive tract to the intestine, where they release their mobile, disease-producing form, the trophozoite. *E. histolytica* trophozoites can live in the large intestine and form new cysts without causing disease. They also can invade the lining of the colon, where they kill host cells and cause diarrhea, amebic colitis, acute dysentery, or chronic diarrhea.⁹¹ The trophozoites also can be carried through the blood to other organs, most commonly the liver and occasionally the brain, where they form potentially life-threatening abscesses (Fig. 210.1). Important virulence factors include the trophozoite cell-surface galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)-specific lectin that mediates adherence to colonic mucins and host cells,^{84,97} cysteine proteinases that likely promote invasion by degrading extracellular matrix and serum components, pore-forming proteins involved in killing of bacteria and host cells, and trophocytosis.^{61,91,101}

The interface of the Gal/GalNAc lectin with the host mucins lining the intestine is the defining moment of the infection.²⁰ If the parasite

FIG. 210.1 Life cycle of *Entamoeba histolytica*. Infection normally is initiated by the ingestion of fecally contaminated water or food containing *E. histolytica* cysts. The infective cyst form of the parasite survives passage through the stomach and small intestine. Excystation occurs in the bowel lumen, where motile and potentially invasive trophozoites are formed. In most infections, the trophozoites aggregate in the intestinal mucin layer and form new cysts, resulting in a self-limited and asymptomatic infection. In some cases, adherence to and lysis of the colonic epithelium, mediated by the galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)-specific lectin, initiates invasion of the colon by trophozoites. Neutrophils responding to the invasion contribute to cellular damage at the site of invasion. When the intestinal epithelium is invaded, extraintestinal spread to the peritoneum, liver, and other sites may follow. Factors controlling invasion, as opposed to encystation, most likely include parasite “quorum sensing” signaled by the Gal/GalNAc-specific lectin, interactions of amebae with the bacterial flora of the intestine, and innate and acquired immune responses of the host. (From Haque R, Huston CD, Hughes E, et al. Amebiasis. *N Engl J Med*. 2003;348:1565–73.)

lectin attaches to the host mucin glycoproteins that line the intestinal lumen, a noninvasive gut infection ensues. The life cycle continues as the trophozoites reproduce by clonal expansion in the mucin layer. Subsequently, the Gal/GalNAc lectin, along with mucin glycoproteins or other gut bacteria, initiates the developmental pathway leading to encystment.^{27,108}

Colitis is caused when the trophozoite penetrates the intestinal mucous layer, which otherwise acts as a barrier to invasion by inhibiting amebic adherence to the underlying epithelium and by slowing trophozoite motility.²⁰ Invasion is mediated by the killing of epithelial cells, neutrophils, and lymphocytes by trophozoites, an action that occurs only after the parasite lectin engages host GalNAc on O-linked cell surface oligosaccharides.^{85,91} The interaction of the lectin with glycoconjugates is stereospecific and multivalent.¹¹⁷ The identity of the high-affinity intestinal epithelial cell receptor is unknown. Secretion of amebapore, a 5-kDa pore-forming protein, by the ameba may contribute

to killing together with trophocytosis.^{59,91} Activation of human caspase 3, a distal effector molecule in the apoptotic pathway, occurs rapidly after amebic contact, and caspases are required for cell killing in vitro and for the formation of amebic liver abscesses in vivo.^{49,116}

Interaction of the parasite with the intestinal epithelium causes an inflammatory response marked by the activation of nuclear factor- κ B and the secretion of cytokines.^{26,77,102} The development of this epithelial response may depend on trophozoite virulence factors, such as cysteine proteinase and macrophage migration inhibitory factor homologue of *E. histolytica*, and leads to intestinal abnormalities through neutrophil- or macrophage-mediated damage.⁷⁷ Neutrophils also can be protective, and activation of neutrophils or macrophages by tumor necrosis factor- α or interferon- γ kills amebae in vitro and limits the size of amebic liver abscesses.^{7,22} In contrast to the intense inflammatory response that is typical of early invasive amebiasis, inflammation surrounding well-established colonic ulcers and liver abscesses is minimal, given the degree of tissue damage.¹⁶

The initial lesions of clinical amebiasis often are small interglandular ulcers with a diameter of approximately 1 mm. They extend only to the muscularis mucosa.^{16,69} The margins may be hyperemic, and slight edema of the surrounding mucosa is present. *E. histolytica* organisms seen in these ulcers stain well with periodic acid-Schiff stain.⁸⁶ Bleeding and friability are not prominent at this stage, although proctoscopic examination may find mucus coming from these ulcers, with an abundant number of amebae present.

The next stage of intestinal disease is the production of deeper ulcers. These "buttonhole" ulcers may be 1 cm in diameter and may extend into the submucosa.^{16,86} The ulcer often extends laterally under normal-appearing mucosa, to form a characteristic flask shape. Occasional perforation through the serosa leads to peritonitis or pneumoperitoneum.¹⁰⁷ Extensive necrosis may be present, but usually only very little inflammation occurs. The edema is more intense, but the mucosa between ulcers is normal, in contrast to the marked inflammatory response seen in bacterial enteritis. When ulceration is more extensive, the edema surrounding the ulcers becomes confluent, and the mucosa appears gelatinous. In young children, this condition can progress to fulminant necrotizing colitis associated with transmural necrosis. The pathologic events associated with this phenomenon are not understood. Rarely, an inflammatory response is present, resulting in granulation of the tissue with a fibrous outer wall.⁸² It is given the name ameboma. Occasionally, an ameboma fills a significant portion of the lumen and causes stricture or obstruction. Other complications of intestinal amebiasis result from direct extension of the ulcers. This extension may result in cutaneous involvement of the perianal area or lesions of the penis, vulva, vagina, or cervix.^{2,82} Cutaneous and ophthalmologic amebiasis also is caused by fecal contamination of the face.⁷²

Amebae disseminate to the liver in 50% of patients with fulminant amebiasis.^{2,3} Dissemination to other organs directly from the intestine probably does not occur, but dissemination from the liver to lung, heart, brain, spleen, scapula, larynx, stomach, and aorta has been described.¹⁶ Amebic abscess of the liver occurs more often in men than in women by a ratio of 16:1 but occurs equally often in prepubertal children of both sexes.^{3,16} Abscesses occur more commonly in adults but occur in children as young as 4 months of age.⁷⁸ These abscesses vary from microscopic lesions to massive necrosis of 90% of the liver. Fever, right upper quadrant pain, and the presence of serum antibodies to amebae point to amebic liver abscess.⁹⁵ Examination of the fluid from such an abscess frequently reveals a reddish, "anchovy paste" fluid that rarely may appear white or green. The fluid is acidic, with a pH ranging from 5.2 to 6.7.⁹³ Amebae are found in the walls of the abscess and only rarely in the fluid of the abscess. Many patients with amebic liver abscess also have anaerobic bacteria in the abscess fluid.⁹⁴ The walls are composed of a thin connective tissue capsule. The right lobe of the liver is involved with amebic liver abscess about six times as often as the left lobe. Abscesses in the right lobe can perforate and cause disease below the diaphragm or in the thoracic cavity. Abscesses in the left lobe can lead to pericardial effusions, which are less common than pleural effusions.^{34,51}

Pleural effusions can remain loculated or lead to cutaneous fistulas or to bronchopleural fistulas. Drainage from these fistulas is acidic, in

contrast to the neutral secretions in the normal lung. Seeding of the cardiac valves and of the brain has been described.¹⁶ Cerebral abscesses have the same microscopic findings as do liver abscesses, with a thin capsule of connective tissue surrounding a fluid with little or no associated inflammatory response.

IMMUNITY

Protection from amebiasis, including acquired immunity to infection and invasion by *E. histolytica*, is associated with a mucosal immunoglobulin A antibody response against the carbohydrate recognition domain of the parasite Gal/GalNAc lectin.^{35,38,40,57} Cell-mediated immunity in protection from invasive amebiasis, but not infection per se, also has been shown. Substantial evidence from an in vivo animal model and more recently from human studies indicates an important role for interferon- γ and interleukin-17 in protection from amebic colitis, by acting in part by activating of macrophages to kill the parasite.^{17,35,44,47} Invasive amebiasis rarely occurs in persons with human immunodeficiency virus infection or acquired immunodeficiency syndrome, even in areas where amebiasis is common; this finding suggests that an important role also exists for natural immunity or innate immune responses, or both, in protection from infection.^{7,37,39}

CLINICAL MANIFESTATIONS

Intestinal Amebiasis

Asymptomatic Intraluminal Amebiasis

The most common type of amebic infestation is an asymptomatic cyst-passing carrier state. All *E. dispar* infections and 90% of *E. histolytica* infections are asymptomatic, manifesting as only *Entamoeba* cysts in the feces.^{31,32,88}

Entamoeba histolytica-Associated Diarrhea

Diarrhea is the most common manifestation of amebic disease, present in 9% of children in the Mirpur cohort each year, compared with only 3% of children having amebic colitis each year.⁴³ *E. histolytica*-associated diarrhea is defined as three or more unformed stools in a 24-hour period accompanied by a new episode of *E. histolytica* infection. This definition was validated previously in the cohort by the following: (1) showing that diarrhea was approximately five times more common in the setting of a new infection (age-adjusted odds ratio for the association of new *E. histolytica* infection with diarrhea of 4.7; 95% confidence interval, 2.9 to 7.6); and (2) showing by a complete bacteriologic, virologic, and parasitic workup that only 32% of patients with *E. histolytica*-associated diarrhea were coinfecting with another pathogen compared with identification of an enteropathogen in 59% of all cases of diarrhea.⁴⁰

Acute Amebic Colitis

Amebic dysentery is defined by a diarrheal stool sample containing occult or gross blood that is positive for *E. histolytica* antigen. Seventy percent of patients have a gradual onset of symptoms over 3 or 4 weeks after infestation, with increasingly severe diarrhea as the primary complaint, accompanied by general abdominal tenderness. Occasionally, the onset may be acute or may be delayed for several months after infestation. This onset differs from bacterial causes of dysentery, in which patients usually have symptoms of only 1 to 2 days' duration. The diarrhea is usually associated with pain in children. Pain may be of such severity that an acute abdomen is suspected.^{52,86} The stools contain blood and mucus in virtually all cases.^{2,86,87} Fever is present in only a few patients with amebic colitis. Abdominal distention and dehydration occur in less than 10% of patients. In young children, intussusception, perforation, peritonitis, or necrotizing colitis may develop rapidly.^{10,52,107} Amebic colitis has been shown to be associated with cognitive disability as a long-term sequela.¹¹⁰

Ameboma

Unusual manifestations of amebic colitis include toxic megacolon (0.5% of cases, usually requires surgical intervention), ameboma (granulation tissue in colonic lumen mimicking colonic cancer in appearance), and

a chronic nondysenteric form of infection that can manifest as years of waxing and waning diarrhea, abdominal pain, and weight loss (easily misdiagnosed as inflammatory bowel disease).

Extraintestinal Amebiasis

Amebic Liver Abscess

The typical patient with an amebic liver abscess in the United States is an immigrant, usually Hispanic, Asian, or a Pacific Islander; is male; is 20 to 40 years old; and has fever, right upper quadrant pain, leukocytosis, abnormal serum aminotransferase and alkaline phosphatase levels, and a defect on hepatic imaging study. Roughly 90% of patients with liver abscesses are men. The abscess usually is single and is in the right lobe of the liver 80% of the time.⁵³ Most frequently, patients have liver abscess without concurrent colitis. Amebae are infrequently seen in the stool at the time of diagnosis of liver abscess.³ Liver abscess can manifest acutely as fever and right upper abdominal tenderness and pain or subacutely as prominent weight loss and, less frequently, fever and abdominal pain. The peripheral white blood cell count is elevated, as is the alkaline phosphatase level, in many patients.

Early evaluation of the hepatobiliary system by ultrasonography or computed tomography (CT) is essential to show the abscess in the liver. The differential diagnosis of the lesion in the liver includes pyogenic abscess, hepatoma, and echinococcal cyst. Aspiration of the abscess occasionally is required to diagnose amebiasis (although amebae are visualized in the pus in only a few cases; if the abscess is pyogenic, the responsible bacteria are seen or cultured). Antibodies to *E. histolytica* are present in the serum of 70% to 90% of patients on acute presentation with amebic liver abscess and are useful diagnostically, especially in combination with antigen detection or PCR tests.⁴² Unusual extraintestinal manifestations of amebiasis include direct extension of the liver abscess to pleura or pericardium and brain abscess. In a patient who has right upper quadrant pain, ultrasonography, CT, or magnetic resonance imaging (MRI) should be performed to examine the liver and gallbladder.

If a space-filling defect in the liver is observed, the differential diagnosis includes the following: (1) amebiasis (most common in men with a history of travel or residence in a developing country); (2) pyogenic or bacterial abscess (suspected in women, patients with cholecystitis, older persons, patients with diabetes, and patients with jaundice); (3) echinococcal abscess (an incidental finding because echinococcal abscess should not cause pain or fever); and (4) cancer. Most patients with amebic liver abscess have detectable circulating antigen in serum and serum antiamebic antibodies.¹

In children, abdominal pain is infrequently reported with amebic liver abscess.^{36,73} More commonly, high fever, abdominal distention, irritability, and tachypnea are noted. Some children are admitted to the hospital with a fever of unknown origin. Hepatomegaly occurs frequently, but elicitation of hepatic tenderness is not well documented. In one report, four of five children younger than 5 years of age died of amebic liver abscesses because the diagnosis was not suspected.⁵⁸ Death usually results from rupture of the liver abscess into the peritoneum, thorax, or pericardium, but it may follow extensive hepatic damage and liver failure.^{3,92}

Metastatic Amebiasis

Extra-abdominal amebiasis presumably follows direct extension from liver abscesses, rather than direct dissemination from the intestine.^{3,16} Thoracic amebiasis is the most common type of extra-abdominal amebiasis and occurs in less than 10% of patients with amebic liver abscess.^{16,51} Symptoms depend on the type of involvement. Empyema, bronchohepatic fistulas, or extension of a pleuropulmonary abscess into the pericardium may occur.

Pericardial amebiasis is the next most common form of extraintestinal involvement and may result from rupture of a liver abscess in the left lobe of the liver into the pericardium or through the extension of the right-sided pleural amebiasis.^{16,29,30,34} It is estimated to occur in 3% of patients with hepatic abscesses.³⁰ It manifests as acute pericarditis with cardiac tamponade and, occasionally, as pneumopericardium.²⁹ Amebic liver abscess in the left lobe also may rupture directly into the left side of the chest.⁶⁸

Cerebral amebic abscesses are seen only in persons with amebic liver abscess and were found in 8% of patients with liver abscess discovered at autopsy in one study.⁶² In other studies, lower rates of 0.66% to 4.7% of patients with amebic liver abscess and brain abscesses were reported.^{50,106} Patients with cerebral amebiasis frequently are so ill from the intestinal, liver, and possibly lung involvement that neurologic signs are not always assessed easily. In 18 patients with proven cerebral amebiasis, the initial neurologic examination was normal in 13, and only one patient later developed seizures.

Other foci of infection are rare findings, but amebic rectovesical fistula formation and involvement of pharynx, heart, aorta, and scapula have been reported. Cutaneous extension after the adherence of perforated, inflamed bowel to the skin is an extremely painful and rare complication.^{16,82} This situation also may arise after invasion of the skin occurs from trophozoites emerging out from the rectum.⁷²

DIAGNOSIS

The prevalence of diarrhea caused by *E. histolytica* in the first year of life in impoverished children in the developing world may be as high as 10%.⁷⁵ A heightened suspicion of amebiasis should be present if the patient has been in a developing country as a resident or traveler. The diagnosis of amebiasis should be considered in any child with risk factors who has the following: diarrhea, bloody stools, or stools with mucus; a hepatic abscess; or right upper quadrant pain, abdominal distention, or tachypnea.^{58,73} In a patient with diarrhea, if blood is present in the stool (grossly bloody or occult blood positive), infectious (Shiga toxin-producing *Escherichia coli*, *Salmonella*, *Shigella*, *Campylobacter*, and *E. histolytica*) and noninfectious (inflammatory bowel disease, diverticulosis, arteriovenous malformations, cancer) causes should be considered.

Microscopic Examination of Stool

Before the development of newer antigen detection tests and PCR analysis, amebiasis was diagnosed by examining a stool sample under a microscope to determine whether *E. histolytica* cysts were present. This method often requires more than one specimen, however, because the number of cysts in the stool varies greatly. In addition, stool microscopy has limited sensitivity and specificity. The body's immune system produces macrophage cells that can look like the amebae. Four different amebae (*E. histolytica*, which causes amebiasis; *E. dispar*, which does not cause disease; and *E. moshkovskii* and *E. bangladeshi*, which may cause diarrhea) look identical under a microscope.^{23,100,104}

Polymerase Chain Reaction, Real-Time Polymerase Chain Reaction, and Antigen Detection Tests

Single and multiplex real-time PCR assays have replaced microscopy as the gold standard for the detection of this parasite. Simultaneously, several microplate enzyme-linked immunosorbent assays (ELISAs) and rapid immunochromatographic assays have been developed to detect amebic antigen in stool¹¹⁴; these tests vary in their sensitivities and specificities and often cannot reliably distinguish between *E. histolytica* and *E. dispar*. The *E. histolytica* II ELISA (TechLab) is the only Food and Drug Administration–approved commercially available microplate ELISA known to detect specifically *E. histolytica* Gal/GalNAc-specific lectin and exclude infection by other *Entamoeba* species.⁴² This ELISA exhibits a greater sensitivity than that of the combination of microscopy and culture but a lower sensitivity (79%) and specificity (96%) than that of real-time PCR.⁹⁹ The *E. histolytica* antigen test can be performed rapidly and cheaply, and it can detect infection before symptoms appear. Early presymptomatic treatment can prevent the development of invasive amebiasis and minimize the spread of infection. Moreover, follow-up tests can be performed to confirm eradication of intestinal infection.

Serologic Tests

Serologic tests for antiamebic antibodies also are a very useful tool in diagnosis, with a sensitivity of 70% to 80% early in the disease and approaching 100% on convalescence.^{105,109} The combined use of serologic tests and stool antigen detection or PCR analysis offers the best diagnostic approach.

Noninvasive Diagnosis of Extraintestinal Amebiasis

Amebiasis outside the intestine has been even more difficult to diagnose. Clinical manifestations of extraintestinal disease vary widely, and less than 10% of patients with amebic liver abscesses have identifiable *E. histolytica* in their stools. The TechLab *E. histolytica* II test was reported to detect Gal/GalNAc lectin in the sera of 22 of 23 (96%) patients with amebic liver abscess tested before treatment with the anti-amebic drug metronidazole and 0 of 70 (0%) controls. After 1 week of treatment with metronidazole, more than 80% of patients became serum lectin antigen negative. Detection of *E. histolytica* Gal/GalNAc lectin in the sera using the TechLab *E. histolytica* II kit is sensitive to diagnose hepatic and intestinal amebiasis before the institution of metronidazole treatment.⁴² One report noted that a real-time PCR assay detected *E. histolytica* DNA in 49%, 77%, and 69% of blood, urine, and saliva specimens, respectively, from patients with amebic liver abscesses.⁴¹

Noninvasive diagnostic procedures such as ultrasound, CT, and MRI can detect extracolonic amebiasis in the liver, paracecal masses, brain, and other sites, but they cannot distinguish between abscesses caused by amebae and those caused by bacteria, thus hampering proper treatment of the condition. Most patients with amebic liver abscess have a single abscess in the right lobe of the liver, although multiple lesions also can occur.⁴ Chest radiographs show the elevation of the right diaphragm in 56% of patients with hepatic abscess.³ The diagnosis of cerebral amebiasis requires careful neurologic evaluation and radiographic evaluation with either CT or MRI.^{16,50,62} In one case, *E. histolytica* DNA was detected by PCR in the central nervous system to make the diagnosis.¹⁰⁶ Because of the risk for perforation, barium studies are relatively contraindicated in patients with amebic colitis.

Biopsy Studies

The colonic and rectal mucosa in amebic colitis usually reveals ulcerations with a diameter of 1 to 10 mm. Amebic trophozoites often are at the periphery of these necrotic areas, which can be sampled through a biopsy specimen taken during sigmoidoscopy or colonoscopy.^{46,53} Because of the potential for perforation, colonoscopy should be undertaken with caution.

In patients with amebic liver abscesses, amebic trophozoites are found near the capsule of the abscess. Until more recently, the most accurate diagnostic test involved examination by microscopy of a sample collected from the abscess tissue by needle aspiration, a procedure that is relatively insensitive and risky and that identifies amebic trophozoites only 20% of the time. PCR, in contrast, is a sensitive and specific means to identify *E. histolytica* in liver abscess material.⁴¹

Differential Diagnosis

Invasive amebic colitis may resemble ulcerative colitis, Crohn disease of the colon (inflammatory bowel disease), bacillary dysentery, or tuberculous colitis.^{11,19,46,102} Stool *E. histolytica* antigen or PCR analysis, colonoscopic examination with biopsies, and serologic examination should be able to differentiate amebic colitis from these diseases. Histologic examination of involved colonic mucosa should differentiate amebic colitis, with its lack of inflammation and rare granulation tissue, from the inflammatory responses seen in ulcerative colitis, bacillary dysentery, and Crohn disease of the colon. Tuberculous colitis and Crohn disease are more likely to show granuloma formation than amebiasis. Ileocecal or small bowel involvement as seen on barium studies would suggest Crohn disease or tuberculosis of the gastrointestinal tract, rather than amebiasis. Tuberculous colitis is usually associated with pulmonary tuberculosis and with a strong reaction to tuberculin skin testing. In some cases, differentiating between invasive amebic colitis and inflammatory bowel disease may be impossible. If a patient with this differential diagnosis is administered corticosteroids and his or her condition deteriorates, the corticosteroids should be stopped, and repeat investigation for amebiasis should be performed.^{19,73,82}

Amebic liver abscess must be differentiated from pyogenic abscesses and neoplastic lesions. Detection of *E. histolytica* Gal/GalNAc lectin in the sera using the TechLab *E. histolytica* II kit was helpful in one study to diagnose hepatic and intestinal amebiasis before the institution of metronidazole treatment.⁴² Total leukocyte counts and cultures of blood

may help to differentiate pyogenic and amebic abscesses. Many children with pyogenic liver abscesses have negative blood culture results, however. Often, amebic and pyogenic liver abscesses show similar features on CT and MRI. Occasionally, nuclear imaging with gallium is helpful because, in contrast to a pyogenic abscess, very few neutrophils are contained within an amebic liver abscess.^{96,98} Gallium scanning of an amebic liver abscess may reveal a cold spot, possibly with a bright rim. For someone with risk factors for amebiasis, several investigators recommend instituting treatment for amebic abscess for 3 or 4 days while serologic, antigen detection, or PCR results are awaited.^{41,73} Patients with amebic liver abscess should respond to treatment in this length of time by becoming afebrile. No change in size of the liver or size of the abscess should be noted at this time because resolution of the abscess usually takes 2 months to several years.^{4,89,90,103,115}

COMPLICATIONS

Complications of amebiasis may be prevented by early establishment of diagnosis and initiation of treatment with appropriate agents.^{50,73} When complications occur, the prognosis generally is worse.

Invasive intestinal amebiasis has been associated most commonly with perforation and peritonitis,^{8,10,52,73,107,113} which apparently are end results of “necrotizing” or “toxic” amebic colitis. In children, perforation may be heralded by the appearance of an acute abdomen or pneumoperitoneum, with rapid progression to death, presumably from sepsis.^{8,73,113} Surgical resection and therapy for endotoxic shock improve the prognosis.¹¹³ This complication is not rare and accounts for more than 30% of deaths from amebiasis in children.^{11,54} Massive intestinal hemorrhage causes approximately 3% of deaths from amebiasis. Multiple colonic strictures also can occur and cause obstructive symptoms. Fistulas to other organs or to the skin may develop.

Liver abscesses are unusual manifestations of amebiasis in children, but their resultant complications account for approximately 40% of all deaths from amebiasis.⁵⁴ Liver abscess also was found in 13% of patients with amebiasis at postmortem examinations. Liver abscess with rupture into the abdomen was present in 8% of patients who died of amebiasis, and rupture of a liver abscess into the right pleural space was found in 12%.⁵⁴ Many patients with amebic liver abscess also have anaerobic bacteria in the abscess fluid.⁹⁴ In cases free of bacterial contamination, the fluid has few inflammatory cells and an acidic pH. Amebic pericarditis or pneumopericardium occurs rarely and is found in only 1% of patients whose deaths were caused by amebiasis.^{29,30,34,54} The fluid is similar to that found in the pleural space. A cerebral abscess was found in 4% of patients with amebiasis who died.⁵⁴ It has been reported in fewer than 10 children, only one of whom survived.^{9,16,50,62} Other complications include infections of the retroperitoneal space, stomach, spleen, esophagus, and duodenum.⁶²

TREATMENT

Intestinal Amebiasis

Asymptomatic Intraluminal Amebiasis

Therapy for asymptomatic colonization differs from therapy for invasive infection. Asymptomatic infections may be treated with intraluminal agents, such as paromomycin or diloxanide furoate. Each agent has a high rate of success for the eradication of cyst passage.^{70,71} Paromomycin is a nonabsorbable aminoglycoside that is active against the cyst and trophozoite stages. High cure rates have been reported with a 7-day oral dose of paromomycin at 25 to 35 mg/kg per day in three divided doses (Table 210.1). Diloxanide furoate (Furamide), which is not approved by the Food and Drug Administration, is a poorly absorbed agent that is quite active against only intraluminal amebiasis.⁶⁶ Cure rates have been greater than 90% with a 10-day oral course of diloxanide furoate at 20 mg/kg per day in three divided doses (maximum, 1500 mg/day).^{70,71,83}

Acute Amebic Colitis

Nitroimidazoles, particularly metronidazole, are the mainstays of therapy for invasive amebiasis.⁴⁰ The oral dosage of metronidazole is 35 to 50 mg/kg per day (maximum, 2250 mg/day) in three divided doses for

TABLE 210.1 Pediatric Dosage of Drugs for Amebiasis

Type of Disease	Drug	Dosage
Asymptomatic colonization	Paromomycin	25–35 mg/kg/day in 3 doses × 7 days
Mild to moderate intestinal disease	Metronidazole	35–50 mg/kg/day in 3 doses × 7–10 days
	Tinidazole	50 mg/kg/day (maximum, 2000 mg) × 3 days
Severe intestinal and extraintestinal disease	Metronidazole	35–50 mg/kg/day in 3 doses × 7–10 days
	Tinidazole	50 mg/kg/day (maximum, 2000 mg) × 3 days

7 to 10 days for severe intestinal or extraintestinal amebiasis. Metronidazole is concentrated in the ameba, probably by reduction of its nitro group by ferredoxin or flavodoxin-like electron transport proteins, which maintain a gradient for the entry of the unchanged drug. Metabolic intermediates of metronidazole damage DNA and possibly other macromolecules, and they deprive the organism of reducing equivalents by acting as an electron sink. Nitroimidazoles with longer half-lives (tinidazole, secnidazole, and ornidazole) are better tolerated and allow shorter periods of treatment.⁴² For children 3 years of age or older, the oral dosage of tinidazole is 50 mg/kg per day (to a maximum of 2000 mg/day) for 5 days for severe intestinal or extraintestinal amebiasis (see Table 210.1).

Approximately 90% of patients who present with mild to moderate amebic dysentery have a response to nitroimidazole therapy. In the rare case of fulminant amebic colitis, adding broad-spectrum antibiotics to treat intestinal bacteria that may spill into the peritoneum is prudent; surgical intervention occasionally is required for acute abdomen, gastrointestinal bleeding, or toxic megacolon.⁴⁰ Agents such as metronidazole that are active against invasive and extraintestinal amebiasis are well absorbed and do not stay in the lumen long enough to have an effect on intestinal amebiasis. Parasites persist in the intestine in 40% to 60% of patients who receive nitroimidazole. Nitroimidazole treatment should be followed with paromomycin or the second-line agent diloxanide furoate to cure luminal infection.⁴² Metronidazole and paromomycin should not be given at the same time because diarrhea, which is a common side effect of paromomycin, may render assessing the patient's response to therapy difficult.^{54–56}

Extraintestinal Amebiasis

Amebic Liver Abscess and Metastatic Amebiasis

Extraintestinal and severe intestinal amebiasis must be treated with tissue-active agents. Metronidazole, 35 to 50 mg/kg per day in three divided doses for 7 to 10 days, is preferred because it is effective and relatively free of serious side effects (see Table 210.1).^{2,3,66,96,98} It is effective for extraintestinal amebiasis in any location, although amebic brain abscesses usually are not treated successfully with any medications. Most patients with amebic liver abscess respond to metronidazole within 72 hours. For amebic colitis, follow-up therapy with a luminal agent is very important because of the high rates of asymptomatic intestinal colonization in patients with amebic liver abscess.

Therapeutic aspiration of an amebic liver abscess occasionally is required as an adjunct to antiparasitic therapy. Drainage of the abscess should be considered in patients who have no clinical response to drug therapy within 5 to 7 days or patients with a high risk of experiencing a rupture of the abscess, as defined by a cavity with a diameter of more than 5 cm or by the presence of lesions in the left lobe.¹¹² Because many patients with amebic liver abscess also have anaerobic bacteria in the abscess fluid,⁹⁴ the addition of antibiotics, drainage, or both to the treatment regimen in the absence of a prompt response to nitroimidazole therapy is reasonable. Image-guided percutaneous treatment (needle aspiration or catheter drainage) has replaced surgical intervention as the procedure of choice for reducing the size of an abscess.¹¹²

PROGNOSIS

The invasive disease develops in 50 million people each year, and 50,000 to 100,000 deaths result.^{88,95,96} The case-fatality ratio is between 1:500 and 1:1000 diagnosed cases. Among patients with illness severe enough to require hospitalization, the case-fatality ratio is higher. One small study in children reported a 9% mortality rate and a 27% morbidity rate.⁷³

Bowel necrosis or perforation is the cause of death from purely intestinal amebiasis, and early surgical intervention can reduce the mortality rate of these complications from 100% to 28%.¹¹³ Amebic liver abscess has a case-fatality rate of 10% to 15% in combined figures of adults and children.^{58,78,92} The mortality rate, when pleural involvement is noted, is 14%.^{51,58} Amebic pericarditis has a case-fatality rate of 40%.³⁴ Cerebral amebiasis is fatal if untreated.¹⁰⁶

FUTURE CONSIDERATIONS

Amebiasis could be prevented by eradicating fecal contamination of food and water. Providing sanitation and safe food and water for all children in developing countries is an important and achievable goal but will require massive societal changes and monetary investments. An effective amebiasis vaccine is a desirable and feasible goal to help the approximately 1 billion people living in unsanitary conditions. The high incidence of amebiasis in community-based developing country studies of infants, who bear the brunt of morbidity and mortality from diarrhea, suggests that an effective vaccine would improve children's health.

The finding that humans naturally acquire partial immunity against intestinal infection indicates that barriers to stimulating an effective acquired immune response should not be insurmountable. Aiding vaccine design is the demonstration that several recombinant antigens, including the Gal/GalNAc-specific lectin, provide protection in animal models of amebiasis and that human immunity is linked to intestinal immunoglobulin A against the lectin.^{35,38,40} The high degree of sequence conservation of the Gal/GalNAc-specific lectin suggests that a vaccine could be broadly protective. Finally, the absence of epidemiologically significant animal reservoirs suggests that herd immunity could interrupt fecal-oral transmission in humans. The challenges will be to design vaccines capable of eliciting durable mucosal immunity, to understand the correlates of acquired immunity, and, most important, to enlist the continued support of industrialized nations to combat diarrheal diseases of children in developing countries.

Blastocystis hominis and related *Blastocystis* species are among the most common gastrointestinal protists of humans, with a worldwide prevalence that may be greater than 50%.^{36,39} The infection is believed to be more common in low- and middle-income countries. Other *Blastocystis* spp. have been described from numerous other vertebrates and insects.³⁸ Although new information about the molecular and cell biology of this organism has been acquired in recent years, considerable controversy about its true taxonomy and life cycle remains.^{5,36,39,42,43} The pathogenicity of *B. hominis* and its ability to cause gastrointestinal illness in humans are equally controversial. Some evidence links *B. hominis* infection to irritable bowel syndrome (IBS),²⁸ but emerging evidence also indicates a role of this protist in the normal human microbiome.^{3,12,13,15,19,33} Investigators have also suggested that *B. hominis* infection may cause human gastrointestinal disease indirectly through the process of dysbiosis, including alteration of normal microbiota.²⁸

ETIOLOGY AND PATHOGENESIS

Since its discovery in the early part of the 20th century by Alexeieff⁷ and then Brumpt,⁷ *B. hominis* has been assigned to many different phyla in animal and plant kingdoms. Early on, it was identified by various workers as vegetable material, a yeast, a fungus, or a protozoan. Although the organism was identified as a polymorphic protozoan parasite in 1967, its subphylum status bounced between the Sporozoa and the Sarcodina.⁵ Nucleic acid sequencing data now suggest that *B. hominis* does not belong to either category,^{18,16} but instead it probably constitutes its own group (class Blastocystea) more closely related to the stramenopiles, a heterogeneous group of unicellular and multicellular protists that includes slime nets, water molds, and brown algae.³⁹ Additional molecular taxonomic data suggest that the intraspecific variation among stocks of *B. hominis* is sufficiently different to warrant multiple separate species assignments for the organism.^{6,39} Currently at least 19 subtypes are recognized within the *Blastocystis* genus, including 9 subtypes found in humans (ST1-9),⁴¹ with ST1 and ST3 the most common subtypes isolated from humans.³⁵ The differences among the subtypes ultimately may have a bearing on the current controversies surrounding the pathogenicity of the organism and its different modes of transmission (i.e., zoonotic and human to human).³⁹ ST3 is believed to be of human origin, whereas the others may be zoonotically transmitted to humans from a variety of animal sources.³⁸ The genome of the ST7 subtype has been completed and shown to have an incomplete oxidative phosphorylation chain and a partial Krebs cycle despite the presence of mitochondria-like organelles.⁹ These mitochondria-like organelles have been shown to increase in number after metronidazole treatments.³⁰

Ultrastructural data gathered from light and electron microscopy on organisms obtained from in vitro culture and from fresh fecal material indicate the existence of at least six different parasite forms. These include cyst forms; ameboid forms; and the so-called granular, avacuolar, vacuolar, and multivacuolar forms.^{5,35} The *B. hominis* vacuolar cell is the most distinctive and appears as a thin peripheral band of cytoplasm surrounding a large, membrane-enclosed central vacuole.⁵ The central vacuole may have a storage function. Although *B. hominis* is thought to have predominantly anaerobic metabolism, structures that look like mitochondria have been identified on transmission electron microscopy. As noted earlier, *Blastocystis* mitochondria may function in only lipid biosynthesis and not oxidative phosphorylation.^{5,42} Several highly speculative life cycles of *B. hominis* have been proposed.^{5,16} The infective stage probably is a dormant cyst form that undergoes excystation in response to host gastric acid and intestinal enzymes. Excystation may result in the release of avacuolar forms that can undergo facultative

transformation to either an ameboid form or a multivacuolar form. The multivacuolar form either may encyst to an infective stage or may coalesce to the vacuolar form.⁵ These stages are thought to predominate in the large intestine, although organisms also have been recovered from duodenal aspirates. Which, if any, of these life cycle stages invades tissue or causes disease is unknown. Acquisition of knowledge in this area has been hampered by the lack of a suitable animal model, although infection of gnotobiotic guinea pigs with this organism was reported to result in mild intestinal hyperemia and superficial invasion of *B. hominis* into the mucosa of the cecum. Nonspecific inflammation (infiltration of lymphocytes and plasmocytes) and edema of the colonic mucosa have been seen during sigmoidoscopy with biopsy in some patients.⁵ So far, except in a subset of patients with IBS who reportedly show elevated immunoglobulin G2 antibody,¹⁴ no serologic antibody response to the organism has been shown.⁸ Evidence for the role of *B. hominis* in the pathogenesis of IBS has been reviewed.²⁸ Among the proposed mechanisms are proteases either secreted by *B. hominis* or on the surface of the microorganism that are proinflammatory, glycosyltransferases that perturb intestinal tight junctions, and indirect mechanisms in which *B. hominis* causes dysbiosis of the gut microbiome.²⁸ The possibility remains that *B. hominis* is entirely commensal in humans or represents a normal component of the human microbiome.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

B. hominis has a worldwide distribution in tropical and temperate regions, with infection rates of 54% among some populations.^{2,4,5,10,11,26,25,33,40} Developing countries, including Brazil, Egypt, and Indonesia, appear to have a higher prevalence than developed countries.^{4,38,38} High rates of infection also have been reported in persons with a recent history of travel,³² with exposure to pets or farm animals,¹⁰ and living in institutionalized settings.⁵ In many of these people, however, *B. hominis* probably is a commensal parasite. Although *B. hominis* is found commonly in preschool-age and school-age children,^{26,25,27} children overall do not seem to be at increased risk for acquisition of infection.⁵ Contaminated water may represent the most common source of *B. hominis* transmission.³⁸

Most studies investigating the association between *B. hominis* infection and disease primarily have as their basis clinical laboratory isolates of the organism in patients exhibiting gastrointestinal symptoms. Common clinical complaints include abdominal discomfort, bloating, cramping, diarrhea, and vomiting.² Seroconversion to *B. hominis* antigens has been linked to IBS.^{14,24} The presence of *Blastocystis* nucleic acids from ST3 to ST5 have been linked to increase interleukin levels in patients with IBS.²⁹ Weight loss associated with protein-losing enteropathy also has been described. Infective arthritis also has been reported.¹⁹ Because *B. hominis* commonly is found in symptomatic and asymptomatic persons, some investigators proposed that only very heavy infections result in disease.^{20,34} Many of these studies were not controlled, however. Overall, the most common symptoms ascribed to *B. hominis* infection are abdominal pain and diarrhea.³⁸

Shlim and colleagues³⁴ conducted a large, prospective controlled study in a population of expatriates and tourists in Katmandu, Nepal who were at high risk for development of traveler's diarrhea. These investigators concluded that *B. hominis* in high concentrations was not associated with diarrhea and that the presence of higher concentrations of the organism in stool was not associated with more severe symptoms.³⁴ In a subsequent editorial, several design features were cited that may "weaken the authors' conclusions."¹⁸ At least four other prospective

trials have been conducted; one supported *B. hominis* as a cause of diarrhea, one argued against it, and two others were inconclusive.³² The confusion may be resolved partly by the increasing recognition of separate human subtypes of *Blastocystis*,^{6,16} which may lead to improved molecular diagnostic techniques to distinguish pathogenic from nonpathogenic species. This situation is somewhat analogous to the morphologically identical species of *Entamoeba* (*Entamoeba histolytica* and *Entamoeba dispar*, only the former of which causes colitis). Some investigators believe that by distinguishing among the different subtypes, at least one or more may be identified as pathogenic, especially among immunocompromised patients, including patients who have undergone splenectomy.^{17,38}

DIAGNOSIS

Examination by light microscopy of wet preparations of fresh or concentrated stool usually identifies *B. hominis*. Staining of preparations with iodine or trichrome also is beneficial. Many laboratories attempt to identify the characteristic vacuolar forms, which may be under-represented in clinical material.⁵ Under these circumstances, the services of an experienced technologist are required to identify the less distinctive fecal cyst form.³⁹ Organisms also can be recovered from biopsy material obtained during sigmoidoscopy and colonoscopy.

TREATMENT

Given the controversy surrounding the pathogenicity of *B. hominis*, a prudent approach is to refrain from treating asymptomatic immunocompetent persons.²¹ In patients who have gastrointestinal illness, including IBS, and in whom other pathogens have been excluded, administering a course of antiprotozoal chemotherapy may be reasonable. The results of several drug studies, including three that were placebo controlled, indicate that therapeutic improvements with parasite clearance in symptomatic patients were noted with the use of metronidazole (15–30 mg/kg per day for 7 to 10 days), nitazoxanide (200 mg twice daily for children 4–11 years old and 100 mg twice daily for children 1–3 years old for 3 days), and trimethoprim-sulfamethoxazole (6 mg/kg trimethoprim and 30 mg/kg sulfamethoxazole daily in two equal doses for 7 days in children; 320 mg trimethoprim and 1600 mg sulfamethoxazole daily in two equal doses for 7 days in adults).^{22,38} However, because these drugs are broad spectrum, it is possible that clinical improvement may have been a consequence of treating an unidentified enteric pathogen.³⁸ To date, the scientific community has been unable to fulfill the Koch postulates for members of the genus *Blastocystis*.³⁸ Some investigators have reported symptomatic improvement in patients receiving either metronidazole or tinidazole.^{5,11}

Using an in vitro assay that used metabolic labeling, researchers found that the drugs emetine, satranidazole, furazolidone, and quinacrine were superior in activity to either metronidazole or tinidazole.⁵ These

authors cautioned, however, that the in vitro assay does not take into account the pharmacokinetic properties of the drugs. More recent in vitro testing of ST1, ST3, ST4, and ST8 found that *B. hominis* exhibits minimal sensitivity to metronidazole, paromomycin, and triple therapy consisting of furazolidone, nitazoxanide, and secnidazole; however, sensitivity to trimethoprim-sulfamethoxazole and ivermectin was observed.³¹ A clinical pilot study from Australia reported on the efficacy of triple antibiotic therapy in 10 adult patients with *Blastocystis*-positive IBS.²³ The three-drug (or drug combination) regimen comprised diloxanide furoate, trimethoprim-sulfamethoxazole, and secnidazole for 14 days, and it was shown to clear *Blastocystis* infection in 60% of patients, but with inconclusive effects on IBS in this small pilot study, such that larger studies may be required.²³ Ultimately, additional studies that examine drug sensitivities of different *Blastocystis* subtypes may help clarify this situation, but for now the status of treating human *Blastocystis* infection remains controversial.³⁵

Entamoeba coli Infection

212

Peter J. Hotez

Until recently, *Entamoeba coli* was considered to be entirely nonpathogenic and was of interest to the clinician only because of its morphologic similarities to *Entamoeba histolytica* that could result in misdiagnosis. In 1991, several case reports from northern Europe appeared, however, that implicated *E. coli* as a possible cause of infectious diarrhea.^{2,5,10} Two cases of diarrhea associated with *E. coli* have been described in children.²

ETIOLOGY AND PATHOGENESIS

E. coli, similar to other members of the genus *Entamoeba*, has trophozoite and cyst forms. The trophozoite is similar in size to that of *E. histolytica* (15–50 μm) but has a more sluggish motility with short pseudopodia.⁴ The cytoplasm is described as granular, coarse, or frothy and contains numerous bacteria, yeasts, and other food materials.^{4,8} Occasionally,

red blood cells are seen in the cytoplasm, but their occurrence is not nearly as common as in pathogenic strains of *E. histolytica*. During passage through the colon, the trophozoite rounds up and synthesizes a chitin-containing cyst wall. *E. coli* cysts measure 10 to 35 μm and usually contain 8 to 16 nuclei, although occasionally 32 nuclei are seen.

Transmission of *E. coli* infection occurs through the fecal-oral route in the same manner as *E. histolytica* infection. On cyst ingestion, the total number of excysting trophozoites usually is lower than eight.⁴ The *E. coli* trophozoites colonize the lumen of the large intestine. Very little is known about the events by which *E. coli* trophozoites occasionally cause human gastrointestinal illness. Even with a pathogenic *E. coli* strain, the invasive potential of this organism is presumed not to be nearly as great as that of *E. histolytica* because diarrheal disease in patients infected with *E. coli* is not associated with dysentery or accompanied by leukocytosis or elevated serum immunoglobulin A level.¹⁰

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

E. coli is worldwide in distribution, although it occurs more commonly in warmer climates, especially in tropical urban slums, and in some populations of homosexual men.^{4,6} In 1991, Wahlgren¹⁰ described eight patients from Sweden with mild or persistent diarrhea who harbored *E. coli*. Before receiving specific antiamebic chemotherapy, all eight patients had their stools examined repeatedly by the following means: (1) light microscopy, to exclude other protozoa and helminths; (2) electron microscopy, to exclude the presence of some pathogenic viruses; and (3) aerobic and anaerobic culture, to exclude pathogenic bacteria. These patients typically had a long history of loose but not watery stools (without blood or mucus), flatulence, and colicky pain. One patient was a parasitology laboratory technician who had symptoms for more than 15 years. Every patient responded to specific antiamebic chemotherapy.¹⁰ Two children with similar symptoms who also responded to antiamebic chemotherapy subsequently were described in Ireland.² In a more recent study, children in Mexico infected with *E. coli* were shown to exhibit higher percentages of body fat,¹¹ such that *E. coli* amebiasis may contribute to childhood obesity.

DIAGNOSIS AND TREATMENT

E. coli sometimes is difficult to distinguish from *E. histolytica*, particularly because the nuclear structures of their trophozoite stages are similar.³

Some differences exist, however, including the karyosome, which is eccentric in *E. coli* but central in *E. histolytica*, and the cytoplasm, which is coarse and seldom contains red blood cells in *E. coli*, in contrast to *E. histolytica*.³ The differences between the cyst stages of *E. coli* and *E. histolytica* (and *Entamoeba dispar*) are more apparent. The *E. coli* cyst typically has two to four times more nuclei than cysts in *E. histolytica*. The *E. coli* cyst has been reported to become more refractive during fixation so that it often is visualized better in a wet preparation.⁴ With use of the polymerase chain reaction assay it is possible to distinguish *E. coli* from other pathogenic amebas.⁷ A newer Luminex assay has also been developed to distinguish among different ameba species found in human stool.⁹

Generally, *E. coli* still is regarded by most investigators as a commensal organism. In patients with persistent diarrhea whose diagnostic fecal evaluation reveals only the presence of *E. coli*, administering a course of specific antiamebic therapy is reasonable.¹ All the Swedish patients were reported to respond to a 10-day course of diloxanide furoate in a dose of 500 mg three times daily.⁷ Children also may respond to an equivalent pediatric dose of 20 mg/kg per day in three divided doses for 10 days. As of 1994, diloxanide furoate was available in the United States from the Centers for Disease Control and Prevention Drug Service. Alternatively, two children from Ireland (where diloxanide furoate was unavailable) were treated successfully for *Entamoeba coli*-associated diarrhea with metronidazole.²

Giardiasis

Tina Q. Tan

Giardiasis is caused by an infection with the flagellated, binucleated protozoan parasite *Giardia lamblia* (also known as *Giardia duodenalis* or *Giardia intestinalis*). Worldwide, it is one of the most prevalent and important infectious causes of diarrheal illness in humans.⁹⁸ Anton van Leeuwenhoek first described the parasite when examining his own stool under a microscope in 1681. Vilem Lambl described the trophozoite in 1859, and Grassi described the cyst in 1879.⁸² This flagellated parasite, which belongs to the genus *Giardia*, family Hexamitidae, and supergroup Excavata,¹¹⁸ is one of the most ancient eukaryotes and lacks many organelles, including Golgi apparatus, peroxisomes, and mitochondria.⁴³ In 2003, however, mitochondrial genes were discovered in the organism; and the organism has been shown to possess specialized membrane structures, known as mitosomes, that perform the respiratory chain activities of the inner mitochondrial membrane. This finding lends

support to the theory that *Giardia* organisms have become highly evolved and have lost many ancestral characteristics.^{1,4,75,76,99,126,127} For centuries, *Giardia* organisms were thought to be nonpathogenic, but data since the 1980s have shown that *G. lamblia* can be a pathogen that causes both sporadic and epidemic disease.^{34,54}

ORGANISM AND ETIOLOGY

This organism has two morphologic forms: the infectious cyst, which is relatively resistant to chemicals and environmental stresses; and the motile trophozoite, which is responsible for the disease. The trophozoite is pear shaped, with a dorsal convexity and a spiral organelle on its ventral surface. The spiral organelle or sucking disk is the way in which the organism attaches to the epithelial microvillus of the upper small

intestine.⁹³ The trophozoite usually measures 10 to 21 μm in length and 5 to 15 μm in width. It has a complex cytoskeleton that maintains the shape of the parasite and anchors the four pairs of flagella, which emerge ventrally, anterolaterally, posterolaterally, and caudally from the cell body. It also has two diploid oval symmetric nuclei surrounded by nuclear envelopes. These nuclei are each approximately 1 μm in diameter and are located in the anterior half of the cell, at the right and left sides of the longitudinal axis. They live in the small intestine and divide by binary fission. The cyst form is most commonly seen in stool samples and is oval, measuring 8 to 12 μm in length and 5 to 10 μm in width. It contains two to four nuclei and remnants of organelles. Cysts can remain viable for long periods of time (≥ 3 months) in cold water and are resistant to killing by iodine and chlorine, but they can be destroyed by heating to 50°C and by desiccation. This form of the parasite is responsible for transmission among susceptible hosts.^{2,16,17} Six species of *Giardia* have been identified on the basis of the morphologic characteristics of the trophozoite: *G. duodenalis*, *G. agilis*, *G. muris*, *G. ardeae*, *G. psittaci*, and *G. microti*. *G. lamblia*, also called *G. duodenalis*, is the primary pathogenic species in humans and other mammals. All the other species primarily infect animal species and cause no significant disease in humans. The species that infects humans is morphologically indistinguishable from that of other mammals.^{2,54} Isoenzyme and genetic analyses indicate that isolates from infected individuals exhibit high levels of genetic diversity and comprise a large number of genotypes, which can be placed in four groups.¹⁸ The different isolates within groups demonstrate some specificity for infection in various mammals versus humans, but no consistent genetic differences exist between isolates that cause symptomatic versus asymptomatic disease. The genotypes are grouped into two major genetic assemblages (assemblage A and assemblage B) and several minor assemblages (assemblages C, D, E, F, and G) that have very strong host specificities and narrow host ranges. It is believed that humans are infected only with assemblages A and B.³⁴ Studies have demonstrated that in symptomatic infection the correlation between isolate assemblage type and severity of infection is strong; however, the infectivity and pathogenicity of *Giardia* genotypes seem to vary depending on the age, clinical and nutritional status, and immune responses of the host.^{2,59,88,102}

EPIDEMIOLOGY

Giardia infections are ubiquitous, and outbreaks occur in developed and developing countries throughout the world. Cross-transmission and infection occur between domestic and wild animals and humans and between humans.^{30,113} Transmission involves the fecal-oral, waterborne, and foodborne transmission of cysts; thus the level of sanitation and a high intradomiciliary or peridomiciliary concentration of domestic animals are directly related to the prevalence of infection.^{36,61,66,77,111,117} *Giardia* is one of the most common parasites in the United States; it affects persons of all ages and is found in 4.2% to 7% of specimens submitted to the laboratory for examination.⁶⁵ The populations that are affected most frequently include children from birth to 5 years of age, adults 31 to 40 years of age, and backpackers, campers, hunters, and travelers to areas where the disease is endemic.^{60,85} Data from the National Giardiasis Surveillance System of the Centers for Disease Control and Prevention estimate that 2.5 million cases occur each year in the United States.¹⁴¹ Cases per 100,000 population range from 1.4 to 30, with seven states reporting more than 15 cases per 100,000 population. In 2005, Vermont had the highest incidence, with 30 cases per 100,000 population. Cases are more prevalent in boys and men, and rates are highest in children 1 to 4 years of age (children in day care and their close contacts), followed closely by children 5 to 9 years of age and adults 31 to 39 years of age. Most cases are reported in the early summer through early fall.¹⁴¹

Giardia is a frequent cause of diarrhea in day care centers around the world, with infection rates of 1% to 55%.^{3,9,68,89,92,97} Most children are symptomatic, and long-term passage of cysts in some preschool-aged children in day care centers may last for as long as 5 to 6 months after the initial diagnosis. Transmission from these infants and children to adult family members is not an uncommon occurrence; up to 25% of the children have *Giardia*-positive stools. The prevalence rates are highest

in centers with many non-toilet-trained children and staff members who change diapers and prepare food without adequate hand washing. Prevalence rates decline after children are toilet trained.⁹ Sexual transmission may occur with both heterosexual and homosexual contact, but male homosexual behavior is an established risk factor for acquiring *G. lamblia* infection, and cyst passage rates may be as high as 20%.^{57,67,73} Other persons at risk include campers, backpackers, hunters, and other travelers to national parks, wilderness areas, and disease-endemic areas because of vertical transmission from animals and ingestion of untreated drinking water.¹³⁷ Patients who were infected during travel had longer exposures in countries where the prevalence was high.⁶³ *Giardia* has been found to be the most common cause of diarrhea in travelers presenting to travel clinics.^{107,110} In addition, many outbreaks have been reported in municipal water supplies that have not been treated with flocculation or filtration. From 1985 to 1994, *Giardia* was responsible for 44% of the outbreaks of waterborne diarrheal illness in which a cause could be determined. Sixty-four percent of these outbreaks were associated with unfiltered water. According to a sample survey of 66 reservoir sites in Canada and the United States, 81% contained *Giardia* cysts at a concentration of 3 cysts/L before treatment and 1.7 cysts/L after treatment.^{69,70} Treatment of water with iodine preparations kills most cysts, but the cysts are relatively resistant to chlorination. Swimming pools may be another source of infection when pools are used by diapered infants and developmentally delayed persons.¹⁰⁰ A less common mode of transmission is through ingestion of contaminated food, in which as few as 10 cysts may be required to establish infection.^{84,104} Transmission has also been documented through ingestion of green leafy vegetables and culinary bivalves harboring *G. lamblia* shed from coastal and marine life.^{42,114}

PATHOGENESIS

Humans are infected by the oral ingestion of as few as 10 to 25 cysts.¹⁰⁴ If symptoms develop, the onset usually begins after a 6- to 15-day incubation period that often precedes detection of parasites in stool. Excystation occurs in the stomach and small intestine, and the trophozoites are found in large numbers in the upper part of the small intestine, where they closely apply their sucking disks to the mucosa (Fig. 213.1). They may penetrate into the secretory tubules of the mucosa and at times are found in the gallbladder and in the biliary drainage. Scanning electron micrographs of the intestinal mucosa (Fig. 213.2) demonstrate the mechanical damage caused by the presence of the organisms on the mucosal surface. The histologic changes seen in the tissues do not always correlate with the presence or absence of symptoms. Biopsy specimens of the small intestine in children and adults show normal histologic features despite the presence of diarrhea and other symptoms.²⁸ Conversely, flattening of the brush border, damage to mucosal epithelial cells, and slight flattening of the

FIG. 213.1 Trophozoite of *Giardia lamblia* adhering to the intestinal surface.

FIG. 213.2 Scanning electron micrograph of trophozoites of *Giardia lamblia* from an intestinal biopsy. Note the indentations left on the mucosal surface by the parasite’s sucking disk.

villi with increased mitotic index, increased goblet cells, alteration of bile content or duodenal flora, and infiltration with inflammatory cells also may be present.^{29,90,105,140} Studies have demonstrated that *Giardia* disrupts the tight junctional zona occludens, increases permeability, and induces apoptosis in small intestinal epithelial cells. Disruption of the intestinal epithelial cell brush border and inhibition of brush-border enzymes and trypsin may explain the lactose intolerance that commonly develops.^{12,20} In vivo and in vitro studies have established that *Giardia* causes malabsorption of glucose, sodium, and water and hypersecretion of chloride and reduces disaccharidase activity, secondary to shortening of the microvilli in a CD8⁺ lymphocyte-dependent manner, thus resulting in loss of epithelial absorptive surface area.^{6,7,11,22,23,115,116} Disruption of digestion by bile and proteases may produce malabsorption, diarrhea, and resultant malnutrition.

Giardia-infected persons may have a spectrum of manifestations ranging from asymptomatic carriage to acute or chronic diarrheal disease, the causes of which are not well understood. Hypotheses include the following: (1) the parasite as a physical barrier to absorption; (2) disruption of the brush border with loss of enzymatic activity; (3) elaboration of toxins by the parasite; (4) changes in fat absorption in the small intestine; (5) activation of cytokines with mucosal inflammation after damage to enterocytes; (6) luminal competition for nutrients; (7) induction of epithelial cell damage, arrested proliferation, and tight-junctional abnormalities; (8) disaccharidase deficiency; (9) nutrient-dependent growth impairment and decreased villus-to-crypt ratios; and (10) translocation of microbiota across the mucosa.^{19,94,121,122,125} However, it appears that the primary cause of diarrhea in giardiasis is malabsorption.

Host immunity, both the humoral and cellular components, is important in the variable manifestations of giardiasis and in clearance and protection against reinfection with *Giardia*. Persistence of infection in nude mice suggests a role for T-cell activity.^{31,106,124} Humans produce serum immunoglobulin (Ig) G, IgM, IgA, IgE, mast cells, T cells, dendritic cells, and nitric oxide in response to infection.* Studies have shown that IgM and IgG antibody with complement is lethal to *Giardia* trophozoites. In the intestinal lumen, the secretory IgA response appears to play a role in the modulation of infection, as does the migration of infiltrating lymphocytes in the intestinal mucosa.^{27,78,112} The absence of secretory IgA is associated with the inability to clear *Giardia* infection and is associated with the development of chronic giardiasis in humans.^{18,101} Eighty-four percent of human volunteers experienced self-cure in 18.4 days, whereas the remainder became chronically infected.¹⁰⁴ Human milk has been shown to kill the trophozoites of *G. lamblia* by generating toxic lipolytic products.^{43,44,103}

Infection may be severe and difficult to eradicate in immunodeficient persons with antibody deficiencies (e.g., common variable

immunodeficiency, X-linked agammaglobulinemia) or in patients with reduced gastric acidity. Giardiasis long has been associated with hypogammaglobulinemia, nodular lymphoid hyperplasia of the small intestine, and chronic diarrhea.⁵⁵ Patients with hypogammaglobulinemia, absence of plasma cells in the intestinal lamina propria, cystic fibrosis, protein-calorie malnutrition, and human immunodeficiency virus infection (or acquired immunodeficiency syndrome) and patients who are receiving immunosuppressive therapy are more likely to develop chronic giardiasis than are patients with X-linked hypogammaglobulinemia, selective IgA deficiency, and Wiskott-Aldrich or Nezelof syndrome.^{62,91,119}

CLINICAL MANIFESTATIONS

Infection with *Giardia* can result in asymptomatic infection (5–15%), an acute self-limited diarrheal illness (25–50%), or chronic diarrhea and malabsorption, depending on host susceptibility and pathogen genotype virulence.^{6,52,60} The incubation period for giardiasis is 7 to 14 days. Symptoms may vary from mild abdominal discomfort and diarrhea to severe cramping, bloating, and severe, explosive, watery, greasy, foul-smelling diarrhea (Table 213.1).⁵⁷ Patients and caretakers describe a constellation of signs and symptoms, including abdominal bloating, flatulence, and frequent foul-smelling diarrhea. Young infants may exhibit anorexia, weight loss, or a malabsorption syndrome that resembles sprue. Symptoms usually last for more than 7 to 10 days and in the majority of cases clear spontaneously. Stooling patterns vary from normal to mushy, foul-smelling diarrhea (Table 213.2). Gross blood, pus, and mucus are usually not present in the stool, and signs of inflammatory diarrhea, such as tenesmus and bloody diarrhea, do not occur. *Giardia* infection also may lead to disorders at extraintestinal sites. Extraintestinal symptoms may involve the eyes (iritocyclitis, choroiditis, retinal hemorrhages, and “salt and pepper” degeneration involving the retinal pigmented epithelium),^{21,96} joints (reactive arthritis most commonly involving the joints of the lower limbs, particularly the knee and ankle),^{15,58} muscles (hypokalemic myopathy), skin, and circulation and may cause micronutrient deficiencies, iron deficiency anemia, protein-energy malnutrition, and growth and cognitive retardation.^{23,51} One study estimated that one-third of patients infected with *Giardia* will express long-term extraintestinal symptoms, a finding suggesting that this involvement is not as uncommon as previously believed.¹⁴

TABLE 213.3 Drugs for the Treatment of Giardiasis

Drug	Dose	Efficacy (%)	Side Effects
Metronidazole	15 mg/kg/day orally divided 3 times a day for 5–10 days (maximum, 750 mg/day)	80–100	Metallic taste, headache, nausea, vomiting, rash, peripheral neuropathy, neutropenia, disulfiram-like effects
Tinidazole	50 mg/kg, single dose (maximum, 2 g)	80–96	Metallic taste, nausea, vomiting, headache, rash, peripheral neuropathy, neutropenia, disulfiram-like effects
Ornidazole ^a	40–50 mg/kg, single dose (maximum, 2 g)	96–100	Metallic taste, nausea, vomiting, headache, rash, peripheral neuropathy, neutropenia, disulfiram-like effects
Secnidazole	2 g, single dose	90	Nausea, anorexia, abdominal pain
Albendazole ^b	15 mg/kg per day for 5–7 days (maximum, 400 mg/day)	94–100	Anorexia, constipation, neutropenia, elevated liver function test results
Furazolidone	6 mg/kg per day orally divided 4 times a day for 10 days	81–96	Allergic reactions, headache, nausea, vomiting, diarrhea, brown discoloration of urine, hemolysis, disulfiram-like effects
Paromomycin	30 mg/kg per day divided 3 times a day for 5–10 days (maximum, 1.5 g/day)	55–88	Nausea, vomiting, ototoxicity, nephrotoxicity
Quinacrine ^a	6 mg/kg per day divided 3 times a day for 7 days	92–95	Nausea, vomiting, dizziness, headache, yellow or orange skin and mucous membrane discoloration, hemolysis, toxic psychosis
Nitazoxanide	1–3 years: 200 mg/day divided 2 times a day for 3 days 4–11 years: 400 mg/day divided 2 times a day for 3 days ≥12 years: 1000 mg/day divided 2 times a day for 3 days	85–90	Nausea, abdominal pain, diarrhea, anorexia, flatulence, headache, yellow eyes, discolored urine, increased creatinine and serum glutamic-pyruvic transaminase levels

^aNo longer produced in the United States. Can be obtained from Panorama Pharmacy, Panorama City, CA.

^bNot approved by the US Food and Drug Administration for this indication in the United States.

A few patients develop persistent, chronic infection that is associated with severe malaise, headache, weight loss, and diffuse abdominal and epigastric discomfort that is exacerbated by eating. Episodes of diarrhea typically alternate with periods of normal bowel movements and may persist over a period of months. Lactose intolerance may develop in 20% to 40% of patients and persist for weeks after the infection has been eradicated.^{119,138} Children with symptomatic giardiasis may develop steatorrhea and malabsorption of vitamin A, vitamin B₁₂, protein, D-xylose, and iron.^{46,51,123} Anecdotal reports have attributed a variety of other symptoms, including rash, urticaria, arthralgia, reactive arthritis, constipation, biliary tract disease, and gastric infection to giardiasis, but no firm evidence supports *G. lamblia* as the cause of these symptoms.

Cyst passers may be asymptomatic and may serve as a reservoir of infection for others. This fact is particularly important for food handler and day care center outbreaks. Severe, prolonged illness that requires hospitalization occurs in 2 per 100,000 cases, a rate similar to that seen in shigellosis.⁷² Hospital admission for young children and pregnant women usually is required because of volume depletion and failure to thrive.¹²³

Parasitic infection, including giardiasis, should be considered in the evaluation of the child who fails to thrive and in immunocompromised infants and children who have diarrhea or gastrointestinal complaints. It also should be considered in the differential diagnosis of any child who is in day care or who has traveled outside the United States and has gastrointestinal symptoms.^{53,89}

DIAGNOSIS

Obtaining a thorough travel and potential exposure history is important in making the diagnosis of giardiasis. Recent travel to wilderness areas or a national park and travel to developing areas or other endemic areas of the world where fecal-oral hygiene is a problem are important parts of the history in any patient with persistent diarrhea. Demonstration of trophozoites or cysts in the stool on ova and parasite examination is the traditional standard of diagnosis.⁸³ Examination of preserved fecal specimens reveals cysts or trophozoites in most infections. Organisms are excreted in a highly variable pattern; therefore, multiple samples taken on different days are required for detection.²⁶ A single stool sample misses 20% to 40% of the infections, whereas three stool samples miss less than 10% of infections.⁵⁶

Commercially available tests to detect antigen by an enzyme-linked immunosorbent assay (ELISA) have been shown to be rapid and highly sensitive and specific, but they are qualitative and are unable to distinguish among genotypes or detect low levels of infection.^{64,136} The ELISA may be particularly useful in screening during mass outbreaks and assessing cure. Monoclonal antibodies usually are used to detect antigen either by an ELISA or an immunofluorescence assay. Some of these assays have a sensitivity of 91% to 95% and specificities of more than 98%.^{33,79,136} Antigen may be best detected when the stool is preserved in formalin.³³ These tests do not replace microscopic examination of the stool, which is considered to be the standard, because of the possibility of infection with multiple organisms in travelers.

Molecular techniques such as polymerase chain reaction (PCR) are alternative methods that may be used for the specific detection of *Giardia* in the stool. These techniques, in combination with restriction fragment length polymorphism or nested PCR, may be used to genotype the organisms. The sensitivity of detection by PCR is greater than that of microscopy, and PCR is much better for detection of low number of parasites in stool samples.⁸ An advance in PCR-based technology for the detection of *G. lamblia* in stool is the use of real-time PCR. This method, using dual-labeled fluorescent probes targeting the β -giardin gene, is sensitive, is rapid, and may be used to detect *G. lamblia* in stool and to differentiate the major genotypes of the organism. Real-time PCR can be adapted to high-throughput detection for the screening of large numbers of samples, especially in outbreak situations.^{13,49}

Even with the available diagnostic tests, infections may be missed in some patients; and in cases with a high index of suspicion, the organism may be recovered by duodenal biopsy or duodenal aspiration. Invasive techniques may be important diagnostic adjuncts in immunosuppressed patients and in patients with sprue, for whom histologic examination of the bowel also may be important in planning therapy.

TREATMENT

All patients with either cysts or trophozoites in the stool should be treated. Multiple classes of drugs are available for the treatment of giardiasis, each with different clinical properties and efficacies, as shown in Table 213.3.^{5,39,139} The nitroimidazole class of agents includes metronidazole, tinidazole, ornidazole, and secnidazole and is the mainstay of therapy for the treatment of giardiasis. These drugs are administered orally in their inactive probiotic form.³⁹ Of the nitroimidazoles,

metronidazole has been the most extensively studied and widely used worldwide. The mechanism of killing of *Giardia* by the nitroimidazoles involves use of the anaerobic metabolic pathways of the organism. The drug diffuses into the trophozoite, where it is activated and inhibits trophozoite respiration and causes cellular damage by the production of toxic radicals and loss of DNA helical structure, with resulting trophozoite death.^{45,132} Of the nitroimidazoles, tinidazole and metronidazole have demonstrated the greatest in vitro activity.^{25,48} Metronidazole is considered the drug of choice for treatment, with tinidazole as an alternative.^{37,39} Although albendazole has been shown to be curative either in single doses or a 5-day course, it is not approved for use in giardiasis in the United States.^{50,143} Quinacrine, which is inexpensive and has excellent efficacy, also is no longer available in the United States.³⁹ It may cause hemolysis in children with glucose-6-phosphate dehydrogenase deficiency. Furazolidone is an effective alternative and is available in a liquid form. However, it is administered four times a day for 7 to 10 days and is associated with side effects that include rash, nausea, and vomiting. Tinidazole has been shown to eliminate the parasite after single-dose therapy.³⁷ Another member of the 5-nitroimidazoles, secnidazole has been shown to be well tolerated at 30-mg/kg per day (maximum, 2 g) and is an option for therapy.⁴⁵ Paromomycin, an aminoglycoside that is not well absorbed, is the only drug that can be used in a pregnant patient. It is not as effective as other medications in eradicating the parasite but may induce clinical improvement. A 3-day course of nitazoxanide has been shown to treat successfully 85% of children with diarrhea caused by *Giardia*.^{35,108} Although outbreaks in day care centers are common, treating all children in the day care center is not efficacious because recurrence rates are high and a chance of a drug reaction always exists. Treatment is reserved for symptomatic children.

Treatment failures and the development of drug resistance have been reported with all the common agents used to treat *Giardia*, including albendazole, furazolidone, metronidazole, and quinacrine.^{5,71} The prevalence of clinical metronidazole-resistant cases is reported to be up to 20%,^{10,52,128,131,133} with recurrence rates up to 90%.¹⁴² Metronidazole-resistant *Giardia* strains have also manifested cross-resistance to tinidazole.^{128,131,133} Furazolidone-resistant *Giardia* species can be induced both in vitro and in vivo, and this may induce the organism to become resistant more easily to quinacrine.^{80,129,134} *Giardia* resistant to albendazole has been reported to develop rapidly in vitro. Albendazole resistance also develops more easily in *Giardia* strains that are furazolidone resistant, giving rise to multidrug-resistant phenotypes.^{74,130}

Patients with clinically resistant strains have been treated with longer repeat courses or higher doses of the initial agent.^{40,87} However, the most effective means of eradicating these infections seems to be the use of an anti-*Giardia* agent from a different class to avoid potential cross-resistance.^{9,24,41,81,86} For *Giardia* strains that are phenotypically considered to be multidrug resistant, the administration of anti-*Giardia* drugs in combination is a method that may be used for successful treatment of the infection.

Dientamoeba fragilis is a protozoan parasite of the human bowel, commonly reported throughout the world in association with gastrointestinal (GI) symptoms.⁶³ Although discovered in 1908, it was not described in the scientific literature until 1918, by Jepps and Dobell,³⁴ and at that time it was considered to be a rare intestinal commensal. Despite its discovery more than 100 years ago, we know less about this organism than about any other of the commonly encountered enteric protozoan of humans. The details of its life cycle, mode of transmission, and potential as a human pathogen are all poorly defined or lacking completely. Controversy therefore still surrounds the pathogenicity of *Dientamoeba*, with conflicting reports on the pathogenic potential of this organism.²⁴

ORGANISM

Dientamoeba was classified initially in the genus *Entamoeba*. The similarity of *D. fragilis* to flagellates, however, specifically to *Histomonas meleagridis*, the cause of “blackhead” enterohepatitis in fowl, was noted on careful examination under the light microscope.¹⁹ Later studies using various techniques, including microscopic, immunologic, antigenic, electron microscopic, and molecular studies, resulted in the reclassification of *D. fragilis* as a nonflagellated trichomonad.^{6,17,21,20} Genetic studies confirmed recent evolution with trichomonads,^{7,27} with two genotypes detected in DNA encoding ribosomal RNA.³⁵ Genotype 1 seems to predominate in epidemiologic studies.^{52,66} Investigators have proposed that *D. fragilis* could be a heterogeneous species, with variants having similar morphology but different virulence.⁷⁴

Although *D. fragilis* was initially thought to occur only as a trophozoite lacking a cyst stage, more recent studies identified distinct morphologic forms, a putative precystic form and a cyst form in both rodent models and human clinical samples.^{44,70} The frequency in which cysts are found in human clinical samples would lead us to believe that they may not be an aberrant form in this host.⁷⁰

D. fragilis infects the mucosal crypts of the large intestine in close proximity to mucosal epithelium from the cecum to the rectum. The organism ranges in size from 3 to 18 µm in diameter, but usually it is 7 to 12 µm (Fig. 214.1A–C). Although the organisms are found most commonly in the binucleate form, approximately 20% are in the uninucleate form, and a few are multinucleate.²⁴ Each nucleus contains a large, fragmented (four to eight granules) karyosome surrounded by a clear zone with no peripheral chromatin and a fine nuclear membrane.⁶³

Humans seem to be the natural hosts of *D. fragilis*, with only a limited number of reports of nonhuman hosts, including apes, monkeys, and pigs.^{13,32,71} Munasinghe and colleagues⁴⁴ described the successful establishment of a rodent model of *Dientamoeba* infection, and wild rats have subsequently been described as natural hosts of *D. fragilis*.⁵⁰

EPIDEMIOLOGY AND TRANSMISSION

Despite the discovery of *D. fragilis* more than a century ago, both its life cycle and its mode of transmission are unknown; however, two mechanisms of transmission have been postulated.¹¹ One hypothesis is that *D. fragilis* is transmitted in the eggs of *Enterobius vermicularis* (pinworm) in a manner similar to the transmission of *H. meleagridis* in the eggs of the avian nematode *Heterakis gallinae*.¹¹ In support of this theory, many investigators have noted a high frequency of concomitant infection with *D. fragilis* and *E. vermicularis*.^{4,28} Ockert^{47,48} provided the most convincing support for this theory when, by ingesting eggs of *E. vermicularis*, which he had washed with water and exposed to pepsin and hydrochloric acid, he became infected with *E. vermicularis*

and *D. fragilis*. The role of *E. vermicularis* as a vector of *D. fragilis* transmission is supported by two more recent studies that detected *D. fragilis* DNA in DNA extracted from surface sterilized *E. vermicularis* ova.^{49,56} Other investigators, noting a high rate of concomitant infection of *D. fragilis* with organisms causing intestinal infections and negative test results for *E. vermicularis*, have suggested fecal-oral transmission.^{39–41,64,66,79} A study using laboratory rodents demonstrated fecal-oral transmission between mice and from mice to rats, thereby indicating that vectors play no role in the transmission of this organism.⁴⁴

D. fragilis was thought to be uncommon until improved diagnostic techniques were used for detection, including prompt fixation for preserving the organism^{25,29,59} and molecular methods.^{52,65,78} However, when appropriate diagnostic methods are used, *D. fragilis* is found to be more prevalent than *Giardia*.¹² The trophozoites of *D. fragilis* have been noted to be quite sensitive to an aerobic environment.¹⁰ They die and disintegrate within 1 hour in an isotonic salt solution at room temperature; when smeared on slides, they round up and become granular within 15 minutes during microscopic examination at room temperature and low humidity.¹⁰

D. fragilis has been reported worldwide with a prevalence in selected populations of 0.9% to 71%,⁶³ with the higher rates reported in crowded living conditions, such as institutions and communal groups,^{2,40,41} in extended families in close contact,⁷² and in persons traveling outside the United States.^{57,69} A serologic survey in Canada that used indirect immunofluorescence techniques detected antibodies to *D. fragilis* in 87% to 100% of healthy children 1 to 19 years old, a finding suggesting that infection is common during childhood.⁹ Although the antibodies detected in this survey did not absorb when incubated with *Klebsiella pneumoniae* or *Bacteroides vulgatus*, known to contaminate the antigen source of *D. fragilis*, additional studies are needed to confirm the specificity of the assay and to define the seroprevalence in other populations.

CLINICAL MANIFESTATIONS

An overwhelming body of evidence dates back several decades and indicates that treatments that eliminate *D. fragilis* result in significant clinical improvement of patients experiencing GI symptoms.* This finding suggests that *D. fragilis* plays some role in the development of GI disease. Clinical presentation of infection ranges from asymptomatic carriage to various GI symptoms including altered bowel motions, abdominal pain, and diarrhea, often in association with eosinophilia, which is reported in up to 50% of patients.^{14,51,53,68}

However, some reports from Northern Europe support a very different trend. In a study from the Netherlands,¹⁸ *D. fragilis* was detected more frequently in the stools of healthy control subjects (14.6%) than in the stools of subjects with GI complaints (10.3%). A large, case-control comparison study comprising 1515 symptomatic patients and 1195 healthy control subjects detected *D. fragilis* in 390 symptomatic patients at a prevalence of 25.7% and in 446 in the control group at a prevalence of 37.3%.³ This study found that *D. fragilis* was more common in healthy, nonsymptomatic groups than in symptomatic patients. Another study, by de Jong and associates,¹⁶ found higher rates of *D. fragilis* in healthy control subjects when compared with pediatric patients presenting with chronic abdominal pain. These investigators found no differences in symptoms when comparing children with and without *D. fragilis*

*References 1, 5, 10, 14, 30, 31, 36, 37, 42, 52–55, 60, 61, 73, 80–82, 84, 85.

FIG. 214.1 (A) *Dientamoeba fragilis* trophozoites on electron micrography. (B) Light microscopy of trophozoite on modified iron-hematoxylin stain. (C) Phase contrast microscopy of trophozoite in culture (with ingested rice starch).

infection, a finding suggesting no association between chronic abdominal pain and *D. fragilis* infection.

DIAGNOSIS

Infection with *D. fragilis* should be considered in patients with abdominal pain, diarrhea, or both, persisting beyond 1 week when all other causes are ruled out. The diagnosis of dientamoebiasis may be problematic if inadequate laboratory methods are used. Investigation for *D. fragilis* infection should include the collection of at least three stool specimens that are immediately placed in a stool preservative such as polyvinyl alcohol stool preservative to retain the morphologic characteristics of the delicate trophozoite.^{33,59,76} The diagnosis also can be made by permanent stained smear of a fresh or purged fecal specimen.²⁹ Detection

TABLE 214.1 Treatment Options for Dientamoebiasis

Drug of Choice	Alternative Drugs
Iodoquinol Adults: 650 mg PO 3 times daily × 20 days Pediatric: 30–40 mg/kg/day (maximum, 2 g) PO in 3 doses × 20 days	Paromomycin Adults: 500 mg PO 3 times daily × 7 days Pediatric: 25–35 mg/kg/day PO in 3 doses × 7 days Tetracycline Adults: 500 mg PO 4 times daily × 10 days Pediatric: 40 mg/kg/day (maximum, 2 g) PO in 4 doses × 10 days Metronidazole Adults: 500–750 mg PO 3 times daily × 10 days Pediatric: 35–50 mg/kg/day PO in 3 doses × 10 days

PO, Orally.

of the organism seems not to be compromised by use of an “environmentally friendly” mercury-free stool preservative and stain (EcoFix and EcoStain).²⁶

Examination of three fecal specimens properly collected and stained leads to the identification of this intestinal protozoan in 70% to 93% of infected persons.³³ Stool specimens should be collected on alternate days because excretion of *D. fragilis* seems to manifest a cyclic pattern.⁶³ Stool samples should be collected before radiologic studies with barium are done because barium interferes with detection of the protozoa. Other medications interfering with parasite identification include antibiotics, mineral oil, antimalarial agents, antiprotozoal agents, nonabsorbable diarrheal preparations, and bismuth. These substances may interfere with the detection of parasites for 3 weeks.²³

After arrival in the laboratory, stool specimens are processed with the use of a formalin-ether sedimentation concentration technique and are stained with either iron hematoxylin or trichrome and examined by qualified and experienced personnel for the proper identification of *D. fragilis*.²⁴ Diagnostic characteristics of *D. fragilis* on a permanently stained smear include a high percentage of binucleate trophozoites and nuclei without peripheral chromatin, but with four to eight chromatin granules in a central mass.⁶³

Other methods used for the detection of *D. fragilis* include indirect immunofluorescence,⁸ xenic culture,^{43,58,83} and conventional and real-time polymerase chain reaction methods that show excellent sensitivity and specificity, in contrast to microscopy.^{15,62,65,67,78} One serologic test has been developed; however, it is not commercially available, and the high seroprevalence of *D. fragilis* precludes its use as a diagnostic tool.⁹

TREATMENT

Several agents have been used in the treatment of *D. fragilis* infection. However, most treatment data are based only on a small number of case reports. No large-scale double-blind, randomized placebo-controlled trials testing the efficacy of antimicrobial agents against *D. fragilis* have been undertaken.⁴⁵ At present, one of four drugs is recommended for the treatment of *D. fragilis* infection (Table 214.1): iodoquinol, tetracycline, paromomycin, or metronidazole.^{38,53,77,75} However, because of the paucity of clinical studies, tetracycline and paromomycin are considered investigational by the US Food and Drug Administration. Among newer agents, the 5-nitroimidazole derivatives secnidazole and ornidazole seem effective in limited studies, and they have the advantage of longer half-lives, single doses, and fewer side effects.³⁸ Laboratory studies have found that ronidazole, tinidazole, and nitazoxanide are active in vitro.^{22,46}

Iodoquinol, 650 mg three times daily for 20 days, is recommended for adults, and a regimen of 30 to 40 mg/kg per day in three divided

doses is recommended for children. The tablets should be taken with meals. Side effects include abdominal discomfort, diarrhea, anal irritation and pruritus, headache, and dysesthesias of the hands and feet. Paromomycin, 500 mg three times daily for adults and 25 to 35 mg/kg per day in three divided doses in children for 7 days may be more effective than iodoquinol.⁴⁵ Adverse reactions to paromomycin include nausea, abdominal cramps, and diarrhea. It is absorbed poorly after oral administration and is no longer available in syrup form in the United States.

Recrudescence or relapse has been reported after one or more 7-day courses of paromomycin in some children.⁷⁵ Alternative therapy consists of tetracycline hydrochloride or metronidazole. Tetracycline is recommended at a dosage of 500 mg four times daily for adults and 40 mg/kg per day in four divided doses for children for 10 days. Tetracycline may cause GI and central nervous system symptoms. It should not be given to children younger than 9 years of age because it may cause discoloration of the teeth. Metronidazole treatment is recommended at a dosage of 500 to 750 mg three times daily for 10 days for adults and 20 to 40 mg/kg per day divided into three doses for children.⁴⁵ Treatment with metronidazole may cause GI and central nervous system symptoms. Because of the adverse reactions associated with these drugs, the clinician should evaluate the need for therapy carefully in each case and discuss treatment options with the child's family.

Trichomonas Infections

215

Joan S. Purcell • Mariam R. Chacko

Trichomonas spp. are found in animals and humans. The most widely studied member of this species is *Trichomonas vaginalis* because it is the trichomonad most relevant to human disease. Donne first described *T. vaginalis* in 1836 as motile microorganisms in the purulent frothy leukorrhea of women with vaginal discharge and genital irritation.²⁰ Epidemiologic information concerning *Trichomonas* infection is most detailed in the adult population; nonetheless, studies that document the epidemiology of *T. vaginalis* in children and adolescents are available.

MICROBIOLOGY

Trichomonads are acellular flagellated protozoans. The Trichomonadidae family is characterized as mononucleate with an axial organelle that has an undulating membrane. The *Trichomonas* genus includes protozoans that have organelles with three to four anterior flagella and an undulating membrane comprising the posterior flagellum. Five *Trichomonas* spp. infect humans, and three *Trichomonas* spp. infect animals. In humans,

the five species of *Trichomonas* are *T. tenax*, *T. ardin delteili*, *T. faecalis*, *T. hominis*, and *T. vaginalis*.⁶⁹ *T. vaginalis* is the most clinically relevant human trichomonad; the other four species are nonpathogenic. *T. vaginalis* consists of four anterior flagella and a posterior flagellum incorporated into the undulating membrane. *T. vaginalis* can survive but cannot multiply at room temperature. In contrast, *T. hominis* has five anterior flagella and a trailing posterior flagellum, and it can survive and multiply at room temperature. Only *T. hominis* can survive in media without serum and in feces for 24 hours.⁶⁹

EPIDEMIOLOGY

Prevalence

Trichomonas infection is not a notifiable sexually transmitted infection (STI) in the United States. This infection is found in all age groups, from neonates to adults, and is the most common nonviral STI, affecting up to 3.7 billion persons.⁵³ The absence of screening programs and variations in diagnostic tests influence prevalence data, but the emergence of point-of-care and nucleic acid amplification tests (NAATs) has enhanced epidemiologic information in this field of study. For details on newborns, infants, and premenarcheal children, see Chapter 42.

The prevalence of *T. vaginalis* varies greatly, from 5% to 74% in women with the highest rates reported from STI clinics and other high-risk populations.^{13,49,71} In adolescent girls, the prevalence rate ranges from 3.6% to 18% depending on the population studied.^{19,24,38,66} The 2003 to 2004 National Health and Nutrition Examination Survey, which randomly samples the noninstitutionalized civilian population in the United States, found a 3.6% weighted prevalence rate for *T. vaginalis* in sexually active girls and women 14 to 19 years of age by polymerase chain reaction testing.¹⁹ In an inner-city primary care clinic the prevalence of *T. vaginalis* was 14.4% by wet mount and culture in 13- to 19-year-old female patients.³⁸ In an urban pediatric emergency department a prevalence rate of *T. vaginalis* by OSOM *Trichomonas* Rapid enzyme test (Sanofi Genzyme) was 9.9% in 14- to 19-year-old female patients; 25% of the positive test results occurred among 14- and 15-year-olds.²⁴ In another emergency department-based study, using NAAT and rapid antigen testing, the prevalence of *Trichomonas* was 18.4%.⁶⁶

In contrast to girls and women, the prevalence in boys and men is not well studied. Data in adolescent boys are limited. In men attending STI clinics, the prevalence of *T. vaginalis* was 22% to 29% in sexual contacts of women with trichomoniasis, and it was 6% in male patients who had sex with male partners.^{29,40} *T. vaginalis* was found in 58% of 85 young black men 16 to 22 years of age who were sexually active, of whom 69% previously had an STI.⁵⁴ An Internet-based study of self-collected penile swabs was conducted among 1699 men; 42% were African American, 9% were younger than 20 years, and 32% were 20 to 24 years of age. The overall prevalence rate of *T. vaginalis* in swabs returned after requesting kits was 3.7%; it was 2% in 15 to 19 year olds and 6% in 20- to 24-year-olds.²³

Risk Factors

A large epidemiologic neighborhood study isolated *T. vaginalis* in young adults living in neighborhoods with a higher concentration of low-income African Americans. Factors such as immigrant concentration and residential instability were not associated with *T. vaginalis*.¹⁸ Trichomoniasis apparently does not have a seasonal pattern of infection.⁴⁵

Urogenital trichomoniasis occurs more commonly in women than in men and in inner-city patients 20 to 30 years of age.⁴⁵ The rate of *T. vaginalis* infection is increased in the following: African American women; women with other STIs, including gonococcal cervicitis; a vaginal pH shift greater than 4.5; pregnancy; menarche; and after menopause.^{48,69}

Infection with *T. vaginalis* increases in direct relation to the number of sexual partners, and the number of sexual partners, in turn, increases the risk for coinfection with other sexually transmitted organisms, including, but not limited to, *Chlamydia trachomatis*, *Neisseria gonorrhea*, *Mycoplasma hominis*, and human immunodeficiency virus (HIV). Oral contraceptives diminish the rate of infection with *T. vaginalis*, in contrast to an intrauterine device or tubal ligation.⁴⁵ The use of nonoxynol-9

spermicidal cream was not related significantly to a decrease in *Trichomonas* infection.⁶ In another study of 226 women attending an STI clinic, no association was found with patients' age, frequency of coitus, date of most recent coitus, day of menstrual cycle, antibiotic use, contraceptive methods, or symptoms of discharge or pruritus.⁴⁸ The risk for *T. vaginalis* is decreased in the wives of circumcised men.²⁶

Other risk factors for women may involve a change in the normal vaginal flora, such as overgrowth of *Gardnerella vaginalis*, *Bacteroides*, or *Peptostreptococcus*. These bacteria may serve as sources of nutrients for trichomonads and allow them to thrive. In men, sexual contact with a woman infected with *T. vaginalis*, nongonococcal urethritis, or nongonococcal nonchlamydial urethritis was associated with an increased risk for acquiring infection with *T. vaginalis*.⁴¹

In men, age older than 30 years, black race, younger age of sexual debut, and the presence of urethral symptoms are all significant predictors of *Trichomonas* infection.²³

TRANSMISSION

The likelihood of perinatal transmission is high in infants younger than 1 year. In a child or an infant younger than 1 year, *T. vaginalis* may have resulted from transmission within a family without sexual abuse, although the probability of sexual abuse must be considered. Perinatal transmission and transmission of infection through fomites should not be assumed without an investigation for sexual abuse. For details see Chapter 42.

T. vaginalis usually is transmitted sexually in adolescents and adults. In an STI clinic, 60% of husbands of women ($n = 30$) who had chronic, repeated *T. vaginalis* infections had positive culture results for *T. vaginalis*, in contrast to 8% in a control group of 50 men attending the same clinic. *T. vaginalis* has been isolated in two men reporting receptive anal intercourse,¹⁴ as well as in a lesbian couple who denied using penetrative sex toys or having male partners, a finding suggesting that transmission may occur through mutual masturbation.²⁹

PATHOLOGY AND PATHOGENESIS

As noted previously, five species of *Trichomonas* have been identified in humans; the most clinically important is *T. vaginalis*. *T. vaginalis* is not part of the normal flora, but is found in the human vagina, urethra, and prostate. Inoculation experiments with *T. vaginalis* in the mouth and intestines failed to establish infection in these sites.⁶⁹ *T. tenax* is found in the mouth, and *T. hominis*, *T. ardin delteili*, and *T. faecalis* are found in the bowel. *T. tenax* is detected in approximately 5% of patients with *T. vaginalis*. *T. tenax*, *T. ardin delteili*, and *T. faecalis* are part of the normal flora and are nonpathogenic. *T. hominis* can infect humans and is associated with gastrointestinal dysentery. The incidence of *T. hominis* in humans is 0.4% to 3.5%. *T. hominis* is found only rarely in the stools of patients who concomitantly have *T. vaginalis*.⁶⁹

Virulence factors associated with *T. vaginalis* infection have been defined and include adherence, contact-independent factors, hemolysis, and host macromolecule acquisition. Epithelial cell adherence depends on an intact cytoskeleton and *Trichomonas* protein ligands and proteases, which are necessary to activate adherence molecules.^{15,22} Cell contact-independent factors include pH variability and cell-detaching factor, which in vitro inhibit reorganization of cells infected with *T. vaginalis*. *T. vaginalis* produces lactic and acetic acid as by-products of glucose metabolism.¹⁵ These acids lower the pH, which is cytotoxic to epithelial cells. Another metabolic by-product of *T. vaginalis* is cell-detaching factor, which has a cytopathic effect on epithelial cells and increases subepithelial vascularity, thus producing the clinical sign of "strawberry cervix."¹⁵ The activity of cell-detaching factor is optimal at pH 5.0 or greater. Hemolysis is seen only in the presence of live trichomonads. Cysteine proteases seem to be important for hemolysis because introduction of their inhibitors in vitro eliminates hemolysis by *T. vaginalis*.^{11,15}

The addition of metronidazole reduces levels of hemolysis by 50%.¹⁵ The hemolytic activity of *T. vaginalis* is temperature dependent, with maximal hemolysis at 37°C (98.6°F). Hemolysis is inhibited by separation of trichomonads from erythrocytes by a 3-mm filter, a finding suggesting

a contact-dependent mechanism.¹⁵ As a parasite, *T. vaginalis* also depends on host macromolecules for nutrition, including plasma proteins and lactoferrin.

The host responds to *T. vaginalis* infection at the cellular level with polymorphonuclear cells and lymphocyte activity. *T. vaginalis* secretes proteases that are chemotactic to polymorphonuclear leukocytes, with resultant phagocytosis and killing of the trichomonad by oxidative mechanisms.¹⁵ *T. vaginalis* secretions are mitogenic to lymphocytes; they enhance phagocytosis by polymorphonuclear cells and may suppress the host immune response if numerous suppressor lymphocytes are activated.

Estrogen levels in female patients directly correlate with infection at peak estradiol levels, and symptoms may be influenced by vaginal concentration of estrogen.²² In an early study of premenarcheal vaginitis in children 3 months to 9 years of age, *T. vaginalis* infection accounted for only 2.8% to 4.4% of cases of vaginitis in unestrogenized vaginas, in contrast to 50% of infections in fully estrogenized vaginas of patients nearing puberty.²⁵ In asymptomatic male subjects infected with *T. vaginalis*, the prostate gland serves as a reservoir. Men may remain asymptomatic because of the concentration of zinc salts in prostatic fluid, which is cytotoxic to trichomonads.⁴⁰ In symptomatic male patients, *T. vaginalis* may be isolated in specimens from urine, urethral discharge, and semen.^{33,40}

In the host, trichomonads may serve as a vector for bacteria and viruses, as shown by the high coinfection rate with *T. vaginalis* and human papillomavirus. Although bacteria contaminate trichomonads externally, trichomonads are thought to ingest virus-infected cells and destroy them, with the active virus left intact.²⁷ *T. vaginalis* has been implicated in pelvic inflammatory disease (PID) through ascension from the vagina to the fallopian tubes. In vitro studies have shown *Escherichia coli* strains, a part of the normal vaginal flora, intimately attached to trichomonads by glycoprotein strands.³⁴ Trichomonads contaminated with bacteria serve as vectors for the bacteria to produce pelvic infection on reaching the uterus, fallopian tubes, or peritoneum.³⁴ Similarly, a more recent study involving Dutch women attending an STI treatment clinic found that 71% of the women infected with *T. vaginalis* were coinfecting with *M. hominis*. Because of the small sample size, however, whether infection with *T. vaginalis* predisposes female patients to infection with *M. hominis* or whether this coinfection reflects the sexual behavior of the individual person remains unclear.⁷

In contrast, vaginal colonization with *Lactobacillus* spp. was thought to inhibit trichomonal invasion by lowering vaginal pH. In a study of 336 African women 15 to 49 years of age, 199 of whom were pregnant, 31% had positive culture results for *T. vaginalis*, and only 40% of the patients tested positive for *Lactobacillus*. Although the rate of *Lactobacillus* colonization in these African women was low, the high rate of *T. vaginalis* infection was not related to the absence of *Lactobacillus*. Trichomonads may not alter the vaginal flora substantially.⁴⁷ In women infected with *T. vaginalis* in the lower genital tract, however, the aggressive inflammatory response with resultant punctate hemorrhages allows transmission and infection with HIV-1.⁶⁰

A spectrum of severity of disease exists in patients infected with *T. vaginalis*. Some patients are asymptomatic, whereas others experience severe symptomatic inflammation and discomfort. The virulence of *T. vaginalis* isolates varies; whether this variance is caused by the host response or inherent properties of the parasite is unknown. The Golgi apparatus in *T. vaginalis* is a prominent structure and seems to be a key station in the production of adhesins.⁸ Evidence indicates, however, that the dramatic heterogeneity that exists on the surface of the parasite leads to antigenic diversity among different isolates of *T. vaginalis*. In one study, prominent immunogens absent on the surface of *T. vaginalis* isolates led to an enhanced ability of the parasite to cause cytoadherence-dependent killing of HeLa cells in monolayer culture. In addition, only the adherent parasites possessed adhesins, which directly affected cytoadherence and cytotoxicity of the parasites.² The cysteine proteases of *T. vaginalis* may be responsible for the cytoadherence, nutrient acquisition, and cytotoxicity of *T. vaginalis*. These proteinases are shed during the life cycle and growth of *T. vaginalis*. One hundred percent of serum samples from women infected with *T. vaginalis*, but none from normal uninfected women, possessed immunoglobulin (Ig) G to

numerous trichomonad cysteine proteinases. This serum antiproteinase antibody disappeared after the women received effective therapy for the infection.³

Some studies provide insight into the relationship between *T. vaginalis* and HIV infection. Potentially biologic synergy is present between *T. vaginalis* and HIV infection, with a 1.5- to 1.7-fold increased risk for HIV acquisition when *T. vaginalis* is present. *T. vaginalis* probably alters the cervicovaginal epithelium by several interacting mechanisms mediated by toll-like receptors, cytokines, chemokines, and innate immune factors, thereby increasing the risk for HIV infection.⁶⁷ Women with HIV infection with *T. vaginalis* are found to have a higher prevalence of HIV RNA in vaginal secretions than women without *T. vaginalis* infection. A decrease in mean HIV RNA genital shedding among HIV-infected women also has been noted after *T. vaginalis* treatment and over a 1- to 3-month period.⁵ HIV-infected women with *T. vaginalis* alone or with gonorrhea and *Chlamydia* infection also have a 1.9 times higher risk for PID.⁵

IMMUNOLOGY

The interaction between *T. vaginalis* and host immunoglobulins is unclear. In women infected with *T. vaginalis*, specific local antibodies—IgG and IgA—are seen in vaginal secretions. IgA may serve to increase opsonization of the parasite by IgG and result in enhanced phagocytosis. IgG specific for *Trichomonas* cysteine proteases and surface proteins is seen, but it does not help rid the host of infection.³ *T. vaginalis* synthesizes high-molecular-weight proteins with variable surface expression.⁴ Of samples obtained from women infected with *T. vaginalis*, 70% of vaginal washes and 80% of vaginal mucus samples had IgG to a specific *T. vaginalis* surface protein immunogen with a molecular mass of 230,000 Da (P230). In contrast, no antibody to P230 was detected in uninfected women or in detergent extract depleted of P230, a finding suggesting a highly specific antibody.⁴ Clinically, this finding may account for the lack of resistance to repeated *Trichomonas* infections and variable host antibody titers in infected persons.

CLINICAL MANIFESTATIONS

Trichomonas has been isolated from the tracheal aspirates in preterm neonates with respiratory failure and from nasal secretions in a full-term newborn with suppurative nasal discharge and respiratory distress.^{52,64,65} The vagina of an infant may serve as a reservoir of infection that goes unnoticed until the infant is evaluated for fever 5 to 6 weeks after birth. Motile trichomonads and pyuria are seen on examination of the urine. Symptoms resolve after treatment with metronidazole.⁵⁵ Vaginitis, with a purulent foul-smelling discharge and itching, is the most common manifestation of infection with *T. vaginalis* in premenarcheal girls; in some patients, trichomonads may be found in the urine initially, with the development of frank signs of vaginitis 7 to 28 days later.^{27,44}

In adolescent girls *T. vaginalis* causes an infection of the vagina, the urethra, the Bartholin and Skene glands, and the cervix. However, 50% of adolescent girls infected with *T. vaginalis* are asymptomatic.⁶³ *T. vaginalis* infection is associated significantly with purulent discharge, vulvar itching, a “strawberry cervix” (punctate hemorrhagic spots), and vaginal and vulvar erythema. The sensitivity of the other signs and symptoms of *Trichomonas* vaginitis, including vaginal burning, dysuria, urinary frequency, dyspareunia, frothy discharge, and cervical friability, is low.⁷⁰ Although frothy leukorrhea is associated most frequently with *Trichomonas* infection, 29% of the patients with frothy discharge in one study did not have *Trichomonas* infection.⁷⁰ Colpitis macularis or strawberry cervix is pathognomonic of *T. vaginalis* infection, but it is noted in only 2% to 3% of patients. Thus this finding cannot be depended on to establish a clinical diagnosis of *T. vaginalis* vaginitis in most patients.⁷⁰ Using an NAAT, *T. vaginalis* has been isolated from the anorectal canal in 8.8% of women and 0.9% of men who reported anorectal intercourse. The significance of this finding is not completely understood, but it is possible that in women perianal contamination from the vagina occurred.¹⁴ Trichomonads may ascend the fallopian tubes and, if contaminated with bacteria, can produce PID.^{11,34} In HIV-infected girls and women, the risk for developing PID increases significantly with *T. vaginalis* vaginitis.⁵¹

In male patients *T. vaginalis* causes an infection of the urethra, urine, semen, Skene glands, epididymis, and prostate and may manifest as symptomatic urethritis with dysuria secondary to urethral inflammation and discharge, balanitis, and rarely prostatitis. However, 90% of adolescent boys and men infected with *T. vaginalis* are asymptomatic.⁶³ On examination, the discharge often is not visualized. When a discharge is present, it is clear to cloudy, but not grossly purulent. On microscopy, numerous inflammatory cells are seen.^{39,43}

T. vaginalis also may be a cause of chronic nonbacterial prostatitis and may manifest as chronic prostatitis resistant to standard therapy.^{32,43,68} Large numbers of trichomonads have been isolated by culture of prostatic secretions of husbands of women with recurrent *T. vaginalis* infection,⁶⁸ with the highest yield (83%) from prostatic secretions, followed by urethral and urine specimens.⁶⁸ *T. vaginalis* has been reported to be an etiologic agent of epididymitis in men, with purulent urethral discharge, scrotal swelling, and enlargement of the epididymis.¹⁷ Although a rare finding, *T. vaginalis* has been reported to infect the median raphe of the penis.⁶¹

CLINICAL DIAGNOSIS

In girls and women, report of vaginal discharge, the presence of a frothy purulent discharge, vulvar or vaginal erythema, and a strawberry cervix should be suggestive of *Trichomonas* infection. Boys and men tend to be asymptomatic or, if symptomatic, have a purulent urethral discharge and urethral inflammation. If the physician relies on clinical examination alone, 80% of infections may be missed.^{20,62}

Screening and Diagnosis

No recommendations have been provided by the Centers for Disease Control and Prevention (CDC) regarding routine screening of asymptomatic female and male patients because of the lack of studies that adequately tested screening for these populations. However, the agency states that decisions about routine screening may be informed by the local epidemiology of *T. vaginalis* infection. Screening can be considered in high-prevalence settings such as STI clinics and correctional facilities and in persons with multiple sex partners, exchange of sex for payment, illicit drug use, or a history of STI. However, data are lacking on whether screening and treatment using these criteria can reduce any adverse health events or community burden of infection.⁷¹

Routine screening for *T. vaginalis* infection in asymptomatic HIV-positive female patients is recommended by the CDC.⁷¹ Routine screening for *T. vaginalis* infections among adolescent girls in foster care should be considered as a best practice measure in pediatric settings.^{1,28}

Because of the high prevalence of *Trichomonas* infections in girls and women, testing should be performed in symptomatic female patients seeking care for vaginal discharge. In a study that assessed testing practices for *T. vaginalis*, only 45% of symptomatic women at STI clinics were tested.⁴⁹ Local testing policies may be influencing the variations in clinical practice, including the availability of microscopy in clinical settings.

Laboratory Tests

Several tests are currently available, including culture, point-of-care tests, and NAATs.

Point-of-Care Tests

Vaginal microscopy of vaginal secretions continues to be a popular and efficient point-of-care test, especially in urban clinics. However, wet mount examinations are tests that are regulated by the Clinical Laboratory Improvement Amendments (CLIA), may have become a barrier to performing these tests in office-based laboratories.

Wet mount preparations are obtained by swabbing the lateral and anterior vaginal fornices to obtain discharge material with vaginal epithelial cells; the secretions are placed in a tube with normal saline and are mounted on a slide as soon as possible to detect motile trichomonads with flagella. These preparations are easy to perform, and the method is cost effective, but in women its sensitivity is only approximately 51% to 65%.⁷¹ The sensitivity of wet mount preparations has also been shown to decrease from 57% to 22% after douching.²⁰ In addition, the

validity of the result depends on the technical skill of the examiner and the rapidity with which the specimen is examined; cooling greatly affects the motility of trichomonads.⁴² The sensitivity has been found to decrease by up to 20% within 1 hour after collection.⁷¹

Other Food and Drug Administration–cleared point-of-care diagnostic tests for *T. vaginalis* in adolescent and adult women include an immunochromatographic capillary flow dipstick technology (the OSOM Trichomonas Rapid Test, Genzyme) and a direct nucleic acid probe hybridization test for *T. vaginalis*, *Gardnerella vaginalis*, and *Candida* spp. (Affirm VP III Microbial Identification System, Becton Dickinson, Franklin Lakes, NJ).¹⁰ Results of these tests can be obtained in 10 and 45 minutes, respectively. Although the sensitivity of both tests on vaginal secretions is greater than 83% and the specificity is greater than 97%, false-positive test results may occur in low-prevalence populations.^{7,71} These point-of-care tests have not been validated or approved for use in genital specimens from prepubertal girls or male urethral specimens.^{28,71}

A positive attitude toward home testing by adolescent female patients 14 to 22 years of age predicted high self-test acceptability, and tampon use was associated with increased self-test comfort.³⁰ Results of patient-collected swabs were in 100% agreement with swabs and tests conducted by a physician.³¹ This finding is helpful for purposes of clinical research and home-based clinical services.

Culture

Culture using Diamond medium (Remel) was the gold standard for detecting *T. vaginalis* infections in vaginal secretion before the NAATs became available.⁷¹ The sensitivity of the culture method is 75% to 96%, and the specificity is 100%.⁷¹ However, the cost of and time taken to process this test in the laboratory, the storage requirements, and the transport requirements of using culture media may be prohibitive for routine office use.

In contrast to wet mount examination, the InPouch (Biomed Diagnostics) method also was found to be significantly more sensitive and specific in one study conducted in young adolescent girls (median age, 13.6 years). This finding underscores the need for accurate testing when using culture-based testing and using InPouch or Diamond medium in cases of sexual abuse.²¹ In men, the combination of prostatic massage before collection of the specimen and culture of urethral samples and urinary sediment has a sensitivity of 94% to 98%.^{41,54}

Nucleic Acid Amplification Tests

NAATs are the gold standard today because they detect *T. vaginalis* infection three to five times more than the wet mount examination.⁷¹ The Aptima *T. vaginalis* test (analyte-specific reagent assay; Hologic) is commercially available, and it is frequently combined with tests for bacterial vaginosis, yeast infection, gonorrhea, and *Chlamydia* infection. The sensitivity and specificity of this test in detecting *T. vaginalis* in vaginal specimens, endocervical swabs, and urine specimens are 95% to 100%.⁷¹ The BD Probe Tec TV Q^x Amplified DNA Assay (Becton Dickinson) is also cleared by the Food and Drug Administration for detection of *T. vaginalis* from endocervical, vaginal, or urine specimens from women.⁷¹ However, no data are available in children.²⁸

Papanicolaou Smear

T. vaginalis may be an incidental finding on a Papanicolaou test, but neither conventional nor liquid-based Pap tests are considered diagnostic tests for trichomoniasis, because false-negative and false-positive results can occur.⁷¹

Other Diagnostic Tests

Acridine orange stain is rarely used in the United States; however, this technique continues to be useful in clinical settings around the world with very basic laboratory resources. Acridine orange stains may permit a rapid, accurate diagnosis of *T. vaginalis* infection and seem to be at least as sensitive as wet mount examination.^{9,56} The dye stains DNA (yellow-green) and RNA (bright red). *T. vaginalis* stains brick red with an oval, yellow-green nucleus. The flagella do not stain. Unfixed smears are kept at room temperature for 24 hours; fixed slides may be kept for 5 days.

TREATMENT

Metronidazole or tinidazole is the treatment of choice for *T. vaginalis* infection, and these drugs are available in the United States. Worldwide, other drugs used for trichomoniasis include nifuratel, nimorazole, secnidazole, and carnidazole. Despite the availability of these other drugs, metronidazole remains the standard therapy for trichomoniasis. Metronidazole enters the trichomonad by passive diffusion, and its nitro group is reduced to a cytotoxic intermediate that reacts with DNA and causes cell death. Metronidazole is 93% to 95% bioavailable; after oral administration, peak serum levels are attained in 1 to 3 hours, and a steady state is attained in 2 to 3 days. Metronidazole is metabolized by the liver, with only 20% protein bound; the drug is distributed well in the body.⁴⁶

Side effects reported with the use of metronidazole include nausea, vomiting, anorexia, a metallic taste, headache, dizziness, diarrhea, and darkening of the urine. Urticaria, reversible peripheral neuropathy, seizures, and ataxia have been reported with intravenous use. The side effects tend to be dose related and self-limited.⁴⁶ In a study of 1199 women with *T. vaginalis* infection who were treated with metronidazole, only 4% to 5% experienced symptoms of nausea, coated tongue, dryness of the mouth, anorexia, or diarrhea. All symptoms disappeared within a few days of completion of treatment, and in only one case was treatment discontinued because of side effects. In addition, relative and absolute leukopenia was not observed in these subjects. Metronidazole enhances or reactivates the growth of *Candida albicans* in the vagina. Metronidazole may potentiate the actions of anticonvulsant agents and warfarin. Because a significant disulfiram-like effect is produced when the drug is combined with moderate intake of alcohol, alcohol should be avoided during and for 48 hours after completion of a course of therapy with metronidazole.⁴⁶

In the United States, two treatment regimens are recommended for treatment of *T. vaginalis*. The first is metronidazole, 2 g orally in a single dose in adolescents. This regimen is 90% to 95% effective.⁷¹ The second regimen is tinidazole, 2 g orally in a single dose. This regimen is 86% to 100% effective. An alternative regimen is metronidazole, 500 mg twice daily for 7 days. Some strains of *T. vaginalis* have reduced susceptibility to metronidazole, with low-level metronidazole-resistant strains reported in 2% to 5% of infected cases. Metronidazole vaginal gel is less efficacious than oral metronidazole and is therefore not recommended.⁷¹ Although rare, higher-level resistance also has been reported.^{50,57,59} Treatment options for metronidazole-resistant cases are limited. If the infection fails to respond to metronidazole, it should be re-treated with tinidazole or metronidazole at 500 mg twice daily for 7 days.⁷¹ If treatment failure continues, the patient can be re-treated with 2 g of metronidazole or tinidazole once daily for 5 days.⁷¹

Treatment of *T. vaginalis* in an HIV-positive adolescent is the same as the standard treatment.⁷¹ However, a randomized clinical trial has demonstrated that the 7-day regimen of metronidazole, 500 mg twice daily for 7 days, is better than the single-dose regimen in HIV-positive patients.³⁶ Metronidazole is a pregnancy category B drug. To date, studies have not been able consistently to show an association between metronidazole use during pregnancy and teratogenic effects in infants. In addition, although some data suggest an increased risk for having a premature or low-birth-weight infant after undergoing metronidazole treatment, limitations of the studies prevent definitive conclusions regarding risks involved in treatment.^{37,71} Treatment during pregnancy may relieve symptoms and prevent pregnancy and perinatal

complications. The CDC recommends counseling all pregnant patients on the potential risks and benefits of treatment. Treatment of all symptomatic women is recommended. In asymptomatic women, deferring treatment after 37 weeks of gestation is an option.⁷¹

Tinidazole is a pregnancy category C drug, and its safety in pregnancy has not been evaluated. It is not offered during pregnancy.⁷¹ A breastfed infant consumes approximately 1% of a single 2-g oral dose of metronidazole; infants of mothers who are breastfeeding and who are treated with a single dose of metronidazole for trichomoniasis should be removed from the breast for at least 24 hours after treatment of the mothers.^{46,71} In the case of treatment with tinidazole, breastfeeding can be resumed 3 days after the last dose.

In children weighing less than 45 kg with *T. vaginalis* vulvovaginitis, metronidazole, 45 mg/kg per day orally in three divided doses (maximum 2 g/day) for 7 days, is recommended. Metronidazole syrup, 200 mg/5 mL, is available.³⁵

The CDC has not recommended partner treatment for *Trichomonas* infection because of inadequate data to support this approach.^{12,71} Nonetheless, it is not unusual for practitioners to prescribe expedited partner therapy for *T. vaginalis*. As more data emerge to demonstrate a decrease in repeat infection with partner treatment, a national policy on expedited partner therapy for *T. vaginalis* may be reconsidered.⁵⁸

PROGNOSIS

If untreated, *T. vaginalis* can lead to chronic inflammation of the Bartholin and Skene glands in adolescent girls and to prostatitis and urethritis with urethral stricture formation in adolescent boys.¹⁶ *T. vaginalis* has been associated with adverse pregnancy outcomes, primarily premature rupture of membranes, preterm labor, and low-birth-weight infants.³⁷ Complete resolution of symptoms in addition to eradication of *T. vaginalis* usually is noted when treatment is provided promptly in all situations. *Trichomonas* infection is also associated with a two- to threefold risk for HIV infection. HIV-positive female patients with *Trichomonas* infections are at increased risk for pelvic inflammatory disease.⁷¹

Balantidium coli is the largest protozoan parasite and the only ciliate to infect humans.^{10,15,23} The organism has a worldwide distribution, but usually it is found in less developed nations of the tropics. Because pigs are the principal animal reservoir, most human infections have been reported in tropical regions where swine have close contact with humans, such as Southeast Asia and the islands of East Asia and the South Pacific (including Thailand, the Philippines, Papua New Guinea, and West Iran) and Central and South America (including the Altiplano of Bolivia).^{3,16,17} High prevalence rates of this infection can be found among pig farmers in this region. Balantidiasis occurs in areas where other swine-associated parasitic zoonoses (e.g., taeniasis, trichinellosis, ascariasis) also are prevalent, although infection with *B. coli* occurs rarely. In Iran, where pig raising no longer is permitted, wild boars serve as an animal reservoir.¹⁸ The organism first was described in 1857 by Malmsten, who observed the ciliates from two patients in Sweden.⁵

ETIOLOGY AND PATHOGENESIS

The organism has trophozoite and cyst stages. The trophozoite is a large, pear-shaped organism covered with cilia. Estimates of size range from 50 to 100 μm in length and 40 to 70 μm in width.¹⁰ This enormous protozoan organism typically can be seen by light microscopy using only low-power magnification.¹⁰ Subcellular organelles, such as a cytostome and many large vacuoles containing bacteria and debris, are visualized under higher magnification. Similar to many other ciliates, *B. coli* trophozoites have a macronucleus and a micronucleus. The trophozoites colonize the large intestine, where ultimately they round up and secrete a cyst wall as they pass down the lumen. The cysts measure 50 to 70 μm and also contain a macronucleus and a micronucleus. The cyst stages can survive in the outside environment and are infectious to a wide range of animals, including humans (see later discussion).

Frequently, *B. coli* does not invade human tissues and does not cause clinical disease. Under conditions that are not well understood, however, *B. coli* also has the potential for highly aggressive invasion and destruction of tissue. Whether the invasive potential of *B. coli* results from parasite virulence, compromised host defenses, or some combination of these two factors is unclear. The observation that invasive disease occurs more commonly in debilitated patients and in patients with polyparasitism suggests that host defenses have an important role in limiting tissue destruction by *B. coli*.^{1,15}

When parasite invasion occurs, it begins in the colonic mucosa, where ulcerations and secondary microabscesses can result. Extensive tissue damage in the cecum and appendix results in clinical presentations of typhilitis and appendicitis.^{7,8,15} Histopathologic examination of these tissues reveals flask-shaped ulcerations and necrosis with an extensive inflammatory infiltrate composed predominantly of polymorphonuclear leukocytes.^{7,15} *B. coli* probably creates mucosal ulcerations through the release of histolytic enzymes similar to those described from *Entamoeba histolytica*.¹⁹ Ulcerations can lead to hemorrhage or even colonic perforation. A second type of histopathology has been reported in which patients harboring *B. coli* develop inflammatory polyposis of the rectum and sigmoid colon.¹⁴

When tissue invasion is extensive, the organism can metastasize to extraintestinal sites and cause hepatic and pulmonary involvement. Polymorphonuclear inflammatory cell infiltration results in abscesses at these sites.^{5,8,14} Most patients with metastatic balantidiasis have recognizable defects in host defenses.¹⁴

EPIDEMIOLOGY

As noted earlier, human balantidiasis has a worldwide distribution, but epidemic foci have been reported in the swine-producing areas of Papua New Guinea, West Irian, Micronesia, the Seychelles Islands, the Philippines, and Central and South America.^{5,16,21} Incidence rates can be high among swine farmers and slaughterhouse workers. The potential for development of human *B. coli* infections is thought to be high in areas of poor hygiene where extensive contact occurs between humans and pigs. The major risk factors include close contact between pigs and humans, inadequate sanitation, and subtropical or tropical climates that favor survival of the infective cyst stages.¹⁷ A notorious outbreak of human balantidiasis occurred after a devastating typhoon on the Pacific island of Truk caused widespread contamination of ground and surface water supplies with pig feces.²¹ Many other animals, including nonhuman primates, guinea pigs, horses, cattle, and rats, also potentially can serve as reservoir hosts. *B. coli* also colonizes many great apes, including baboons, orangutans, chimpanzees, and gorillas, and clinical balantidiasis has been reported in these primates when they are maintained in captivity.¹⁵ Human epidemics also have been described in institutional settings, especially where crowding mixes with low levels of personal hygiene.²¹ In these instances, human-to-human spread has been postulated. Although *B. coli* is not known as an opportunistic pathogen in patients infected with human immunodeficiency virus, at least one case of *B. coli* in this setting has been described.⁵

CLINICAL MANIFESTATIONS

Asymptomatic Infection

Most infections are asymptomatic or cause occasional loose stools. This situation probably accounts for 85% of patients harboring *B. coli*.¹⁵ Asymptomatic infection may occur more commonly in children than in adults.²²

Diarrhea

The next most frequent presentation of *B. coli* infections is in patients who have intermittent diarrhea, abdominal pain, and weight loss.²² Sometimes, discrete ulcerations can be observed during sigmoidoscopy.¹⁵ Chronic diarrhea has been described in a patient with acquired immunodeficiency syndrome.⁴ A subset of patients with balantidiasis subsequently develops invasive disease.

Invasive Colonic Balantidiasis

The hallmark of *Balantidium colitis* is dysentery with bloody and mucous stools, colonic tenderness, leukocytosis, and fever. Sigmoidoscopy and colonoscopy of these patients reveal ulcerations and formation of mucosal granulomas.^{1,15,21} Involvement of the large intestine can be diffuse, although in some cases, right-sided colonic lesions predominate. Right-sided colonic lesions can progress to typhilitis or appendicitis.^{7,8,15} Transmural involvement of the colon frequently results in intestinal obstruction, hemorrhage, and balantidial peritonitis. Colonic perforation is an ominous complication that is associated with extremely high mortality rates.¹⁵

Metastatic and Extraintestinal Balantidiasis

Highly invasive balantidiasis leading to metastatic disease of the mesenteric lymph nodes, liver, and lung is a rare complication that can occur in malnourished, debilitated, and immunocompromised patients. Pulmonary infection with *B. coli* has been described.¹⁷ A case of

extraintestinal disease associated with pulmonary hemorrhage and iron deficiency was described, possibly as a result of inhalation of pig manure.¹³ *B. coli* has been rarely reported as a urinary tract pathogen linked to hematuria^{2,12} and as a cause of vertebral osteomyelitis.⁶

DIAGNOSIS

Stools from patients harboring *B. coli* have been described as having a pigpen odor.²² The examination of wet preparations of fresh or concentrated stools usually reveals cyst and trophozoite forms of *B. coli*. Cilia motility and rapid rotary motion of the trophozoites occasionally can be appreciated under low-power magnification. Because the organism takes up heavy concentrations of dye, stained preparations typically do not reveal internal structures or even cilia.¹⁰ These large organisms can be confused with helminth ova, especially on stained preparations.¹⁰ As an adjunct to direct fecal examinations, sigmoidoscopy can show ulcerations from which abundant trophozoites may be obtained for diagnosis.²² Bronchoalveolar wash fluid containing *B. coli* has been reported; investigators have suggested that diagnosing such lung infections can be problematic because of the potential to confuse ciliated *B. coli* with ciliated pulmonary epithelial cells.¹⁷

TREATMENT

For the treatment of intestinal balantidiasis, numerous chemotherapeutic regimens have been tried, usually with some improvement. In many cases, the parasite is not eradicated, however.¹⁵ For children older than 8 years of age, tetracycline, 40 mg/kg per day in four doses for 10 days (maximum, 2 g/day), is the treatment of choice.²⁰ Tetracycline is considered to be investigational for this condition by the US Food and

Drug Administration. Also considered investigational for balantidiasis are the drugs iodoquinol, 30 to 40 mg/kg per day (maximum, 2 g) in three doses for 20 days, and metronidazole, 35 to 50 mg/kg per day in three doses for 5 days (maximum dosage, 2 g).^{9,11} Nitazoxanide also may be effective.¹⁷ Alternative chemotherapeutic agents that have been tried with variable success include paromomycin and chloroquine.¹⁵ Surgical intervention often is required for gastrointestinal invasive complications of *B. coli*, such as typhlitis, appendicitis, and peritonitis.

Cryptosporidiosis

217

Poonum S. Korpe • A. Clinton White Jr

Cryptosporidium is an important cause of acute diarrhea in normal hosts worldwide, of persistent diarrhea in children in developing countries, and of chronic diarrhea in immunocompromised hosts, including patients with acquired immunodeficiency syndrome (AIDS).^{42,83,124,195,218} These protozoan parasites were identified first in the stomach of mice in 1907,²⁰⁹ and for decades they were considered to be veterinary pathogens. The first human cases of cryptosporidiosis were reported in 1976.^{140,160} In the early 1980s, large numbers of cases were noted with the emerging epidemic of AIDS.⁵¹ Thereafter, *Cryptosporidium* was identified in animal handlers and children,^{51,223} and it was associated with large waterborne outbreaks of diarrhea.^{53,130} Studies have shown that *Cryptosporidium* is a common cause of diarrheal disease in immunocompetent and immunocompromised hosts. More recent studies using more sensitive techniques suggest that it is an under-recognized cause of moderate to severe diarrhea in Africa and Asia. *Cryptosporidium* is thought to be second to rotavirus as a cause of diarrhea morbidity worldwide.^{113,195}

MICROBIOLOGY

Cryptosporidium spp. are ubiquitous, small (4–6 µm), obligate intracellular protozoan parasites that infect the epithelium of the gastrointestinal

tract of vertebrates. *Cryptosporidium* was previously classified within the subclass Coccidia, along with *Cystoisospora*, *Cyclospora*, and *Toxoplasma*, but this may soon change.²¹⁸ Species names were given according to the animal that they infected.⁶¹ Initial cross-transmission studies revealed that little host specificity exists. Subsequent genetic studies have identified at least 26 accepted species of *Cryptosporidium* and more than 45 *Cryptosporidium* genotypes.^{33,122} At least 15 species have been documented to cause human infection.^{19,33} Most human infections are caused by separate species, *C. hominis* and *C. parvum*. *C. hominis* is found mainly in humans (but can infect gnotobiotic pigs), and *C. parvum* is found in a wide range of animals (particularly cattle and sheep) and in humans. The relative frequency of *C. hominis* and *C. parvum* in humans differs in geographic regions, probably as the result of differences in transmission routes. In European countries, *C. parvum* was initially found more commonly in human cases than *C. hominis*, although several more recent *C. hominis* outbreaks have been reported throughout Western Europe.^{75,120,184,221} In the rest of the world, *C. hominis* has been the predominant species in humans.^{23,25,225} *C. meleagridis* has been identified in most case series. Humans are less frequently infected with *C. cuniculus*, *C. canis*, *C. felis*, *C. muris*, *C. ubiquitum*, and *C. viatorum*.^{24,37,58,59,70–72} Rare infections have been noted with six other species and four other genotypes.³³

FIG. 217.1 Life cycle of oocyst. After ingestion, the oocysts (a) release the sporozoites (b), which attach to and are engulfed by the epithelial cell. Inside the parasitophorous vacuole, the organisms enlarge to form trophozoites (c) and divide to form meronts (d, e, f). After reinvasion, they may differentiate into the sexual forms (microgamont [g] and macrogamont [h]), which fuse to form the zygote (i). The zygote releases the thin-walled oocysts (k), which cause autoinfection, or thick-walled oocysts (j), which are the infectious form.

LIFE CYCLE

Cryptosporidium spp. can complete their entire life cycles, including asexual (merogony) and sexual (sporogony) reproductive cycles, within a single host (homoxenous). The life cycle is characterized by six major developmental stages: (1) excystation, or release of infective sporozoites; (2) merogony, or asexual replication in the host; (3) gametogony, or the formation of microgametocytes and macrogametocytes; (4)

fertilization, or the union of microgametocytes and macrogametocytes; (5) oocyst formation; and (6) sporogony, or the formation of infectious sporozoites within the oocyst wall (Fig. 217.1).^{19,61,163}

The life cycle begins with ingestion of the infectious oocyst. The oocysts are activated in the stomach (temperature and acid) and upper intestines (bicarbonate, bile, and pancreatic enzymes). This process allows the organisms to excyst, releasing four infective sporozoites.¹⁶³ The motile sporozoites glide over the surface of the epithelium and

bind to receptors on the surface of the intestinal epithelium, thus inducing actin polymerization and protrusion of the intestinal epithelial cell membrane.¹⁶³ The membrane surrounds the sporozoite and fuses to form the parasitophorous vacuole, which remains in the microvillus layer on the surface of the epithelium. Inside the parasitophorous vacuole the parasites undergo asexual reproduction (merogony). They enlarge into trophozoite forms and divide to form type I meronts, which mature and rupture to release the motile merozoites. The merozoites bind to receptors on the epithelial cells and are engulfed by the cells. They then either repeat the process of merogony or undergo sexual differentiation (sporogony).

In the case of sexual differentiation, the merozoites differentiate into the microgametocytes and macrogametocytes. The microgametocyte releases the microgametes, which penetrate the cells infected with macrogametocytes. The macrogametocytes and microgametes fuse to form the zygote form, which then undergoes meiosis to form the oocyst, containing four sporozoites. Two morphologic forms of the oocyst have been described: thin-walled oocysts, which excyst within the same host in a process of self-infection; and thick-walled oocysts, which are shed into the environment.

EPIDEMIOLOGY

Cryptosporidium is distributed worldwide. Infection generally is more common in warm, humid months. Prevalence rates generally are higher in resource-poor countries than in industrialized countries.¹²⁴ Older surveys not involving patients with human immunodeficiency virus (HIV) infection documented oocysts in 1% to 3% of specimens from industrialized countries of Europe and North America and in approximately 10% to 15% of specimens from developing countries.¹²⁴ Most studies on the prevalence of infection have relied on detection of oocysts in fecal samples using acid-fast stains, which are insensitive. However, with the development of improved diagnostic techniques, such as antigen detection, immunofluorescence, and polymerase chain reaction (PCR), the true burden of cryptosporidiosis is being uncovered.^{5,24,42,154,171,190,208} Cryptosporidiosis has been identified as a leading cause of severe diarrhea among young children in low-income countries.¹¹³ A multicenter case-control study of causes of moderate to severe diarrhea estimated 2.9 million cases of cryptosporidiosis in children less than 2 years of age in sub-Saharan Africa and 4.7 million cases in South Asia, with approximately 200,000 *Cryptosporidium*-attributable deaths in these regions.¹⁹⁹

Studies from Peru, Brazil, India, Bangladesh, Guinea-Bissau, and Zimbabwe have documented frequent infections in children during their first 2 years of life.^{4,5,41,104,111,145,151,158,177,213} In a Peruvian birth cohort study of diarrheal disease, the incidence rate of cryptosporidiosis as determined by a serologic assay was higher than the rate determined by stool microscopy (0.77 vs. 0.41 infection/child-year of surveillance).¹⁷⁷ Similarly high seroprevalence rates were noted along the United States–Mexico border.¹¹⁸ Young children in day care centers are at high risk for acquiring infection. Outbreaks of cryptosporidiosis in day care centers have been reported from numerous countries.^{10,46,78,142,214}

Cryptosporidium is also a common cause of persistent diarrhea in immunocompetent and immunocompromised children in developing countries.^{72,152,158,161,198,207,208} A study in West African children investigated episode-specific determinants for the progression of an acute episode of diarrhea to chronic diarrhea; current infection with *C. parvum* was the most significant risk factor.¹⁹⁸ Among 243 children with persistent diarrhea in Uganda, 76 (31%) had *Cryptosporidium* infection.²⁰⁷ Of the 243 children, 91 had HIV infection, of whom 67 (74%) had *Cryptosporidium*. Children with CD4⁺ cell counts less than 25% were more likely to have *Cryptosporidium* infection.²⁰⁷

In wealthy countries, cryptosporidiosis is an important but underdiagnosed problem. The number of cases reported in the United States tripled in the early 2000s, in part because of increased use of diagnostic tests. Currently, approximately 8000 cases are reported per year in the United States (incidence of ~2.6 in 100,000).^{168,226,227} However, the actual number of cases is estimated to be 100-fold higher because of underdiagnosis and underreporting.^{42,192} In England and Wales, more than 4000 cases are reported per year (incidence of eight in 100,000 per

year).³⁸ In both countries, more cases are detected when laboratories use routine testing for *Cryptosporidium* in all stools from children and when more sensitive immunologic techniques are used (instead of stool microscopy).^{34,42,135,174}

Cryptosporidium is a common cause of diarrhea in patients infected with HIV. Cryptosporidiosis occurs in an estimated 10% to 15% of patients with AIDS in developed countries and in 30% to 50% of patients with AIDS in developing countries.¹²⁴ Among patients with HIV infection, the infection rate is proportional to the CD4⁺ cell count. In a longitudinal study of patients with HIV infection, the infection rate varied from 23% of patients with CD4⁺ cell counts greater than 1000/μL to 46% with cell counts less than 100/μL.¹⁷⁵ The widespread use of highly active antiretroviral therapy has resulted in the restoration of immune function and a reduction in the incidence of cryptosporidiosis and other opportunistic infections.¹¹⁷

Cryptosporidiosis also has been noted in other immunodeficient hosts, including patients with primary immunodeficiencies, organ transplantation, cancer, and diabetes.⁹⁷ A particularly high prevalence of cryptosporidiosis occurs in patients with X-linked hyperimmunoglobulin (Ig) M syndrome. In two case series of hyper-IgM syndrome, the prevalence of cryptosporidiosis was 24%.^{88,121} Cryptosporidiosis is also increasingly recognized after solid organ or stem cell transplantation.^{18,114,119}

TRANSMISSION

Humans can acquire *Cryptosporidium* infections through several transmission routes, such as direct contact with infected people (person-to-person transmission) or animals (zoonotic transmission) and ingestion of contaminated water (waterborne transmission) and food (foodborne transmission). The relative importance of these transmission routes varies by species and from country to country.^{19,38,226} For example, foodborne disease has been noted more frequently in Scandinavia than in other regions.⁷⁶ Transmission dynamics are modulated by the low infectious dose, the fact that oocysts are immediately infectious when shed, the resistance of oocysts to chlorination, the stability of oocysts in the environment (especially in water), and the different dynamics of anthroponotic and zoonotic species.

The infectious dose of *Cryptosporidium* is low. In human challenge studies (including *C. hominis*, *C. parvum*, *C. ubiquitum*, and *C. meleagridis*), all organisms demonstrated a low infectious dose, but considerable variability was noted among isolates, ranging from approximately 1000 oocysts (UCP strain) to 10 oocysts (Texas isolate, *C. hominis*).^{39,57,164,165} Because the infectious dose is low, *Cryptosporidium* is transmitted easily from person to person. This route of transmission was recognized initially in outbreaks associated with contact with day care centers^{46,223} and with nosocomial transmission.^{63,109,157,191} Secondary transmission within households also is common.¹³¹ During the acute diarrheal illness, large quantities of oocytes are excreted in stool and are highly infectious. Asymptomatic shedding of oocytes may continue for 5 weeks after an acute episode of diarrhea.²⁰¹ Contact with an ill person is a major risk factor for cryptosporidiosis.^{19,226} Sexual transmission has been postulated to occur in association with anogenital sex.⁸⁹

Cryptosporidium parasites are well adapted to waterborne transmission.^{12,33,94} *Cryptosporidium* oocysts are resistant to environmental conditions; oocysts can remain infectious for at least 6 months if they are kept moist, but viability decreases rapidly with desiccation.^{12,61,163} Oocysts are killed by heat, pasteurization, hydrogen peroxide, ozone, and ultraviolet radiation.^{61,106,163} Oocysts are highly resistant to chlorination, however.¹¹⁰ Surveys have shown that most surface sources of drinking water are contaminated with oocysts before treatment, and even low-grade contamination has been documented in samples of treated water.

Waterborne outbreaks of cryptosporidiosis have been linked to contaminated drinking water, such as water from artesian wells, surface water, and filtered public drinking water,^{54,62} and to contaminated recreational water, such as swimming pools, water parks, lakes, rivers, beaches, and fountains.^{33,94} The largest documented waterborne outbreak of diarrhea occurred in Milwaukee, Wisconsin in 1993, affecting an estimated 400,000 people.¹³⁰ Many of the waterborne outbreaks, including

the outbreak in Milwaukee, have been caused by *C. hominis*. However, both *C. hominis* and *C. parvum* have been implicated in spread by drinking water.^{38,33,115} With improvements in filtration, drinking water is less often implicated in cases in the United States and Europe, but *Cryptosporidium* remains the main cause of illness associated with recreational water (e.g., swimming pools, rivers, lakes, fountains).^{33,94}

The epidemiology varies considerably by parasite species. Studies in the United Kingdom demonstrated that *C. hominis* is associated with the population of young children, international travel, and recreational water.³⁸ Incidence peaks in the fall. By contrast, *C. parvum* infection peaks in the spring and is associated with animal contact, surface water, and private water supplies. Numerous outbreaks have been attributed to animal contact.^{19,38,115} Other species are more frequent in older patients, immunosuppressed hosts (e.g., patients with AIDS), and persons with animal contact.^{25,58,59,70,178}

Foodborne infections occur less commonly.²²⁶ Outbreaks have been associated with contaminated apple cider, unpasteurized milk, chicken salad, and raw produce. Oocysts are found commonly on vegetables in developing countries.¹⁶⁷ *Cryptosporidium* is associated with international travel and causes approximately 6% of traveler's diarrhea.¹⁵⁶

PATHOLOGY AND PATHOGENESIS

In immunocompetent hosts, the organisms are localized primarily to the distal small intestines and proximal colon. In immunodeficient hosts, the parasites have been identified throughout the gut, in the biliary tract, and in the respiratory tract.^{45,80,103} Studies using PCR suggest that respiratory involvement may be underappreciated in children with cryptosporidiosis.¹⁵⁵ Children with persistent cryptosporidiosis may have villous atrophy and a mild increase in lamina propria lymphocytes.¹⁷³ Heavier infection is associated with the following: villous atrophy; crypt hyperplasia; marked infiltration with lymphocytes, plasma cells, and neutrophils^{45,74,79,80,129}; and extraintestinal involvement.

Cryptosporidium causes watery diarrhea, malabsorption, and weight loss. These symptoms are thought to result from sodium malabsorption, electrogenic chloride secretion, and increased intestinal permeability.¹²⁴ In vitro studies demonstrated that *Cryptosporidium* infection directly induces defects in intestinal epithelial cell barrier function in vitro.^{2,81,182} Cryptosporidiosis also is characterized by defects in intestinal permeability.^{79,125,194,228} Increased permeability may result in decreased absorption of fluids and electrolytes and solute fluxes into the gut. Studies in children with cryptosporidiosis have shown a correlation between the severity of disease and altered intestinal permeability.²²⁸ Increased permeability is associated with circulating endotoxin and childhood malnutrition.¹⁵¹

Infection of intestinal epithelial cells leads to activation of nuclear factor- κ B.^{141,181,188} Toll-like receptors and MyD88 are key mediators of this pathway.^{43,185} The main effect of this activation is to inhibit apoptosis of the infected cells. This signaling pathway leads to modulation of microRNAs and secretion of defensins.^{43,163} Increased expression of proinflammatory cytokines and markers of inflammation also occurs, including tumor necrosis factor- α and increased expression of proinflammatory CXCL8, CXCL10, and lactoferrin.^{107,124,163,170} The chemokines and cytokines recruit inflammatory and immune cells into the intestines. Infection also leads to increased expression of cyclooxygenase-2, production of prostaglandins by the epithelial cells, and production of neuropeptides by the inflammatory cells.^{90,116,181} Prostaglandins are thought to mediate decreased sodium absorption and to stimulate chloride secretion. However, prostaglandin inhibitors have not proved to be effective in therapy of human cryptosporidiosis. The neuropeptide substance P correlates with severity of diarrhea in patients with cryptosporidiosis and AIDS and causes many of the defects associated with cryptosporidiosis in a monkey model.^{90,181} Octreotide, a substance P antagonist, partially suppresses diarrhea in patients with chronic cryptosporidiosis.⁶⁸

Cryptosporidiosis leads to villous atrophy and crypt hyperplasia.^{47,79,129,173} Increased epithelial cell apoptosis has been shown in cells from tissue cultures and in biopsy specimens from infected intestines.¹²⁹ Loss of villous surface area is associated with malabsorption.^{45,79,194}

IMMUNOLOGY

Both innate immunity and acquired immunity are important in the defense and clearance of *Cryptosporidium*.¹⁷⁰ Innate responses play a key role in clearance of initial infections.¹³⁶ Some host factors have been implicated in innate responses, including mannose-binding lectins, complement, defensins, natural killer cells, and nonspecific inflammatory responses.^{27,29,43,52,172}

CD4⁺ T cells play a key role in the control of cryptosporidiosis, mainly associated with acquired immunity. Among patients with HIV infection, cryptosporidiosis is self-limited in patients with CD4⁺ cell counts greater than 180/ μ L, chronic in patients with cell counts lower than 100/ μ L, and fulminant in some patients with cell counts lower than 50/ μ L.^{17,64,86,133} Resolution of cryptosporidiosis in patients with AIDS in response to highly active antiretroviral therapy is associated with an influx of CD4⁺ cells into the intestines.¹⁹³ Similarly, Kirkpatrick and colleagues¹⁰⁸ noted an association between major histocompatibility class (MHC) II types (which present antigen to CD4 cells) and susceptibility to cryptosporidiosis.

Interferon- γ (IFN- γ) is an important mediator of the immune clearance of *Cryptosporidium* in murine models.^{12,14,15,19,139,206,211} Similarly, lymphocytes from persons who have recovered from cryptosporidiosis produced IFN- γ after antigen stimulation in vitro.^{2,77} Although seropositive volunteers challenged with *C. parvum* expressed IFN- γ in the intestinal mucosa, biopsy samples from seronegative volunteers in human challenge studies, lymphocytes obtained during active cryptosporidiosis, and stool from children with active cryptosporidiosis lacked IFN- γ expression, even though all had self-limited disease.^{2,5,16,77,107,176,220} Thus the role of IFN- γ in human infections is predominantly in acquired immunity and memory responses. CD8 cells may be important in human infection because they produce IFN- γ in response to parasite antigen, MHC I polymorphisms are associated with risk of infections, and in vitro studies suggest that CD8 T cells clear infection in vitro.^{6,10,12,13,108,169,170,176}

Some IFN- γ -seronegative, normal volunteers were experimentally infected, and in patients with AIDS who were recovering from cryptosporidiosis, interleukin-15 was expressed in the intestines in association with IFN- γ -independent control of infection.^{166,180} This effect likely is mediated by activation of natural killer cells.^{52,136}

The role of antibody in the immune response to cryptosporidiosis is controversial.¹⁷⁰ High levels of serum and fecal antibodies to *C. parvum* have been found in patients with AIDS with chronic cryptosporidiosis and in volunteers challenged with *C. parvum*.^{11,14,48} The presence and timing of antibody correlated with shedding of oocysts, however, rather than with clearance or resistance to infection, and cryptosporidiosis has not been associated with immunoglobulin defects.⁹⁷ However, more recent studies suggest that maternal antibodies in breast milk may be protective.¹¹²

Hyper-IgM syndrome, because of defects in CD40 ligand, is associated with increased frequency and severity of *Cryptosporidium* infection.^{3,7,88,122} This susceptibility is thought to result from profound defects of antigen-presenting cells, production of interleukin-12 and tumor necrosis factor- α , and defective stimulation of IFN- γ production.^{4,98} Other primary immunodeficiencies associated with cryptosporidiosis include CD4 cell deficiency, deficient MHC II, and combined immunodeficiencies.^{97,137,224}

CLINICAL MANIFESTATIONS

The clinical spectrum of disease caused by *Cryptosporidium* is broad and depends on the immunologic status of the host, prior exposure, and parasite species (Table 217.1). Symptoms of cryptosporidiosis develop after a prepatent period, during which the parasites invade the intestinal epithelium and proliferate. The prepatent period, determined from point-source exposures and human challenge studies, is approximately 1 week (range, 1–30 days).^{36,130} However, this period varies considerably with parasite strain and intensity of exposure. Regardless of the immunologic status of the patient, diarrhea is the most common clinical manifestation of cryptosporidiosis. Children present with an acute diarrheal syndrome characterized by watery diarrhea, cramps, and

TABLE 217.1 Clinical Manifestation of Cryptosporidiosis

Host	Clinical Manifestations	Comments
Normal host	Acute watery diarrhea	Relapses common Persistent diarrhea common
Children in developing countries	Acute watery diarrhea Persistent diarrhea	Diarrhea more severe in children with malnutrition Persistent diarrhea affecting nutritional status, growth, and intellectual function
Immunocompromised host	Acute watery diarrhea Relapsing diarrhea Persistent or chronic diarrhea Cholera-like illness Extraintestinal involvement	Transient, self-limited, similar to disease in normal host Very common Usually found in patients with low CD4 count or malnutrition Voluminous watery diarrhea, only with very low CD4 count Respiratory tract, biliary tract, and pancreas

TABLE 217.2 Diagnosis of *Cryptosporidium* Infection

Test Type	Method	Comments
Microscopic examination of stools	Modified acid-fast stain of stools	Inexpensive and widely available diagnostic test
	Fluorescent stains (auramine O, auramine-rhodamine)	Faster than other acid-fast stains and may improve sensitivity
	Immunofluorescent assays	More sensitive than acid-fast staining but also more expensive
Antigen-detection assays	Enzyme immunoassay and immunochromatographic tests: direct and indirect immunofluorescence assay	Good sensitivity (66–100%) and excellent specificity (93–100%), but occasional lots associated with false-positive test results
Molecular methods	Polymerase chain reaction	Increased sensitivity in contrast to microscopic or antigen-detection studies

abdominal pain.^{35,124,218} Other, less common clinical findings include fever, flatulence, nausea, vomiting, shortness of breath, and cough. The stools are occasionally described as foul-smelling, bulky, or containing mucus, but they rarely contain blood and fecal leukocytes. Respiratory symptoms are not uncommon, and lung involvement has been noted frequently.¹⁵³ In immunocompetent patients, the onset of diarrhea is often abrupt, and the illness usually is self-limited. Recurrent symptoms develop in 40% of patients after initial resolution. Relapses may occur after a diarrhea-free period of several days to weeks.^{130,131,158} Forty-five percent of patients have diarrhea lasting more than 14 days.^{159,198}

Cryptosporidium is one of the most common causes of prolonged and persistent diarrhea in developing countries and is responsible for about one-third of cases.^{104,123,152,158,161,198} Children with persistent diarrhea, especially if caused by *Cryptosporidium*, are at high risk for additional gastrointestinal infections after the initial illness, weight loss, and premature death.^{3,7,123,149,150} A long-term follow-up study of children with an onset of cryptosporidiosis before 1 year of age suggests an association with poorer physical fitness and poorer cognitive development that persists for years.⁸⁴

Cryptosporidiosis is more severe in children with malnutrition, and malnourished children tend to have a protracted course and shed oocysts longer.^{148,150,151,189} They often require hospitalization, and the disease may have a fatal outcome.^{8,49,191} Prospective cohort studies of children followed from birth have shown significant differences in nutritional status before acquisition of *Cryptosporidium* infection.^{3,40,148} In addition, the onset of cryptosporidiosis is associated with growth faltering. Older children eventually recovered and experienced catch-up growth, but children infected before 1 year of age often never recovered.^{3,40,148} Asymptomatic infection can lead to malnutrition even without diarrhea.^{15,41,111} A cohort study of Bangladeshi infants found that even a single asymptomatic infection in the first 24 months of life was associated with increased risk of stunting at age 2 years.¹¹¹

The clinical manifestations also vary somewhat by parasite species. In general, *C. hominis* causes more severe disease than other species. Cama and colleagues²⁴ noted more nausea, vomiting, and malaise with *C. hominis* than with zoonotic species. Hunter and colleagues^{96,97} noted that *C. hominis* was more strongly associated with extraintestinal sequelae (e.g., joint pain, eye pain, fatigue).^{36,96}

The clinical manifestations of cryptosporidiosis in patients with HIV vary. Four distinct gastrointestinal syndromes have been described

in HIV-infected patients: (1) transient, self-limited diarrhea, similar to diarrhea in normal hosts, usually in patients with CD4⁺ cell counts greater than 150/μL; (2) voluminous watery diarrhea or cholera-like illness that requires rehydration, seen in a few cases, usually in patients with CD4⁺ cell counts lower than 50/μL; (3) relapsing diarrhea; and (4) a chronic diarrheal illness resulting in wasting, usually in patients with CD4⁺ cell counts lower than 150/μL.^{17,86,129,133,207} The severity and duration of illness in both patients with AIDS and other patients with immunodeficiencies generally depend on the degree of immunodeficiency.

In immunocompromised patients, extraintestinal involvement may occur in the respiratory tract, biliary tract, and pancreas.^{44,86,128,143,212} Respiratory tract involvement often is asymptomatic, but it may cause cough, shortness of breath, wheezing, croup, and hoarseness. *Cryptosporidium* has been reported as a cause of laryngobronchitis in children.⁸⁵ Biliary tract involvement in cryptosporidiosis has been limited to patients with profound immunodeficiency.^{86,212} Patients may have acalculous cholecystitis or cholangitis and, less frequently, sclerosing cholangitis or hepatitis.^{86,203,212} Pancreatitis is an uncommon finding, but it has been reported in adults and children infected with HIV.^{87,128,146} Concomitant infection with cytomegalovirus can occur and frequently is associated with irregularities of the intrahepatic duct.^{13,93,101}

DIAGNOSIS

Many laboratories do not test for *Cryptosporidium* unless the tests are specifically requested (Table 217.2). *Cryptosporidium* infection usually is diagnosed by microscopic examination of stools. Fresh, preserved, and frozen stools can be used for testing, but preservatives may interfere with some assays.^{30,35,197} Numerous concentration methods have been attempted to improve the yield, but formalin-ethyl acetate concentration is the most widely used.^{30,197} The oocysts are small, 4 to 6 μm, and similar in size and shape to yeast forms, and stains that are used routinely to detect other intestinal parasites (i.e., iodine, trichrome, and iron hematoxylin) do not detect *Cryptosporidium*. The method most commonly used by clinical laboratories to detect *Cryptosporidium* oocysts in stools has been the modified acid-fast stain.^{34,174} Oocysts stain pink or red, whereas yeast cells and fecal debris stain green or blue (Fig. 217.2).^{32,37} The sensitivity of stool examination with acid-fast staining is poor, requiring an oocyst concentration of greater than 500,000/mL in formed stools,²¹⁶ with fewer cases detected than with other methods.³⁵ Fluorescent stains (e.g.,

FIG. 217.2 Staining of oocysts.

auramine O, auramine-rhodamine) can be read more quickly than other acid-fast stains and may have improved sensitivity, but positive results require confirmation by a second method.^{35,105,197} Immunofluorescent assays are more sensitive than other microscopic methods.^{35,66,105}

Antigen-detection assays are being used increasingly for diagnosis. Commercial kits for *Cryptosporidium* are available in enzyme-linked immunosorbent assay (ELISA) and immunochromatographic formats. The ELISA kits for *Cryptosporidium* have good sensitivity (66–100%) and excellent specificity (93–100%).^{35,67,66,197} The sensitivity has been poor in some studies, however, and pseudo-outbreaks from false-positive results have been reported.^{31,56} Commercial ELISA kits also may test for *Giardia* and *Entamoeba* antigens. Immunochromatographic tests are rapid tests for *Cryptosporidium* and *Giardia* antigen.^{67,99} The sensitivity is less than with other assays, and results are available in minutes.^{67,99} The specificity was initially reported to be excellent, but a more recent study from Minnesota suggested a poor positive predictive value.^{67,99,179} Antigen assays as a group have the advantage of not requiring skill in microscopic identification of organisms.

Molecular methods such as PCR for *C. parvum* DNA also have been used to detect organisms. These methods have increased sensitivity, in contrast to microscopic or antigen-detection studies of stool.^{5,137,156,197,204} In one study of children with primary immunodeficiencies, PCR was able to detect significantly more cases of biliary cryptosporidiosis than were detected by stool studies.¹³⁷ In general, the number of cases detected increases significantly with molecular methods. Multiplex assays, including for a wide range of enteric pathogens, are in development.¹²⁶ A multiplex assay for enteric pathogens using polymerase amplification and detection with probes attached to beads has been approved in the United States.²⁰²

Biopsy of the intestine typically is unnecessary for the diagnosis of intestinal infection, although the unique apical location within the intestinal epithelium is distinctive. The parasite can be visualized by

light microscopy after staining with hematoxylin and eosin or by electron microscopy.⁵⁰

MANAGEMENT

Replacement of fluids and electrolytes is a crucial first step in management, as with all cases of diarrhea. Oral rehydration is preferred, but severely ill patients may require parenteral fluids. Glutamine supplementation may improve fluid absorption.²⁶ Dietary management is crucial in cryptosporidiosis, especially if it is associated with persistent diarrhea. Supportive care should include initially a lactose-free diet because lactase activity is decreased on the apical border of epithelial cells.¹⁷³

Cryptosporidiosis is associated with increased intestinal transit, which could interfere with absorption of fluids, electrolytes, and drugs.^{20,194} Antimotility and antisecretory agents (i.e., tincture of opium, loperamide, octreotide, and acetorphan) have roles in therapy, but their use generally is limited to refractory cases in adults with AIDS.^{68,196} These agents may control the diarrhea, but they do not eradicate the parasite.

In immunocompromised hosts, management of intestinal cryptosporidiosis is problematic. For patients with AIDS with chronic cryptosporidiosis, effective antiretroviral therapy can result in dramatic improvement in diarrhea.^{28,65,82,132,144,166} The HIV protease inhibitors have anticryptosporidial activity in vitro and reduced infection by 90% in an animal model,^{95,141} and most of the studies reporting responses have used protease inhibitors. In contrast, cryptosporidiosis is associated with malabsorption of nucleosides.²² Similarly, reversal of immunosuppression may be a key component of management of severe cryptosporidiosis in transplant recipients.^{114,119} Patients with X-linked immunodeficiency with hyper-IgM syndrome may respond to a CD40 agonist antibody.⁶⁰

The role of antiparasitic therapy in cryptosporidiosis is controversial. Because cryptosporidiosis usually is self-limited in immunocompetent hosts and can be variable in compromised hosts, controlled trials are crucial. No agent has proved reliably curative in patients with advanced AIDS. A meta-analysis of seven randomized controlled clinical trials found no clear evidence for efficacy of antiparasitic agents in the management of cryptosporidiosis in compromised hosts.¹

Nitazoxanide is a nitrothiazolyl-salicylamide derivative with a broad spectrum of antiprotozoal and anthelmintic activity.¹⁶² Nitazoxanide is active against *Cryptosporidium* in vitro and in animal models.^{69,205} A placebo-controlled study of nitazoxanide in patients with cryptosporidiosis showed significant clinical improvement in apparently immunocompetent children and adults with persistent diarrhea.¹⁸⁶ By day 7, diarrhea had resolved in 39 of 49 (80%) patients treated with nitazoxanide, in contrast to 20 of 49 (41%) patients treated with placebo. Nitazoxanide also reduced the duration of shedding of oocysts. In parallel randomized studies in severely malnourished HIV-infected and HIV-negative children in Zambia with chronic cryptosporidiosis, a 3-day course of therapy not only led to clinical and parasitologic improvement, but also improved survival in HIV-negative children.⁸ All children were treated with nitazoxanide suspension (100 mg twice daily for 3 days) or matching placebo. Among non-HIV-infected patients, resolution by day 7 was noted in 14 of 25 (56%) patients treated with nitazoxanide, in contrast to 5 of 22 (23%) in the placebo group. Similar findings were reported in immunocompetent patients 12 years of age and older. A good clinical response was seen in 27 of 28 (96%) patients receiving nitazoxanide, in contrast to 11 of 27 (41%) patients receiving placebo.¹⁸⁷ Among the HIV-infected children, most with severe malnutrition, no significant response occurred.⁸ A second study using higher doses and prolonged therapy in children with HIV and cryptosporidiosis also did not demonstrate efficacy.⁹

Nitazoxanide suspension was approved in the United States in 2002 for treatment of cryptosporidiosis and giardiasis in children. For most indications, it is administered every 12 hours for 3 days. The recommended dose is 100 mg (5 mL) for children 12 to 47 months of age, 200 mg for children 4 to 11 years old, and 500 mg for patients age 12 years and older (~15 mg/kg per day).²¹⁷ Safety data for use of nitazoxanide in children younger than 12 months are lacking; thus its use in infants is not recommended at this time. Nitazoxanide generally is well tolerated; adverse events occur at a frequency similar to that for placebo and

include abdominal pain, diarrhea, vomiting, and headache.²¹⁷ Although unproved, nitazoxanide and other antiparasitic drugs should be considered as adjuncts to antiretroviral agents or reversal of immunosuppression in children with severe cryptosporidiosis.¹⁴⁷ Combinations of nitazoxanide with other agents (e.g., paromomycin and azithromycin) have been used in some severely compromised patients.

Paromomycin is an orally administered nonabsorbable aminoglycoside. Initial in vitro studies noted poor activity against *C. parvum*. When patients with AIDS and cryptosporidiosis were treated with available antiparasitic drugs, however, some improved when treated with paromomycin.⁷³ Three randomized, controlled trials examined the effects of paromomycin in patients with AIDS and cryptosporidiosis.^{91,102,219} Paromomycin was associated with a significant reduction in shedding of oocysts and decreased stool frequency, but not cure.²¹⁹ In another study, no significant difference was found between groups.⁹¹

Macrolide antibiotics, including spiramycin, azithromycin, roxithromycin, and clarithromycin, have some activity against *Cryptosporidium*.¹⁶ In one study, children treated with spiramycin had shorter duration of symptoms and shedding of oocysts,¹⁸⁸ but a second trial showed no effect.²²² Case series noted improvement in cryptosporidiosis in patients with HIV infection and cancer who were treated with azithromycin,^{55,92,100,155} but subsequent trials in patients with AIDS did not show changes in frequency of stools or shedding of oocysts.¹⁶ A study in Egyptian school children suggested that resolution of symptoms was faster with azithromycin.⁶ Roxithromycin treatment was associated with improvement in AIDS-associated cryptosporidiosis in two uncontrolled studies.^{200,210}

PREVENTION

In hospitals and day care centers, hand washing is the most important measure to prevent the spread of any enteric pathogen. Alcohol rubs may not be adequate. Enteric precautions (i.e., washing hands, wearing gloves, and wearing gowns if soiling is likely) are important measures to prevent nosocomial spread.

Swimming pools are important sources of infection. Contamination of treated recreational water, such as a fecal accident in a swimming pool, should prompt aggressive measures, including closing the pool temporarily.^{32,33} Recreational waters, such as lakes, may pose a danger for compromised hosts, who should avoid contact with untreated water.¹⁴⁷

Control of waterborne transmission of cryptosporidiosis is a major public health concern. This issue is complicated by the ability of *Cryptosporidium* to escape the filtration system used in most public water facilities and its resistance to chlorination. The Centers for Disease Control and Prevention (CDC) recommends that during

outbreak situations, compromised patients boil tap water for 1 minute or filter tap water using a filtration system to remove particles 1 μm or larger, or use bottled water prepared by distillation or reverse osmotic filtration.³⁰ In situations not associated with an outbreak, no special measures are recommended. However, routinely using the outbreak measures outlined earlier for severe immunosuppressed patients may be prudent.¹⁴⁷ The CDC website contains an excellent patient fact sheet about *Cryptosporidium* and its prevention (<http://www.cdc.gov/parasites/crypto>). Currently, no vaccine is available to protect against *Cryptosporidium*. Vaccines for cryptosporidiosis are in developmental stages, but, as of this writing, no vaccines have progressed to human trials.^{21,127,134,138,183,215}

Cyclosporiasis, Cystoisosporiasis, and Microsporidiosis

218

Martin Montes • Seher Anjum • A. Clinton White Jr

CYCLOSPORA CAYETANENSIS

Cyclospora cayetanensis is an intestinal coccidian protozoan parasite, related to *Toxoplasma*, *Cryptosporidium*, *Sarcocystis*, and *Cystoisospora*. This parasite infects the gastrointestinal tract of returning travelers and immunocompromised patients, causing acute diarrheal disease.^{3,67,68,136,194} In 1979, *C. cayetanensis* was first identified by Ashford¹¹ in the stool of a woman and two children from Papua New Guinea. *C. cayetanensis* was identified in four patients with diarrhea after travel to Mexico and Haiti.¹⁶⁵

The organisms were identified in stools from travelers and expatriates in Nepal. Subsequent studies noted an association with diarrhea in patients with acquired immunodeficiency syndrome (AIDS) patients.^{3,136,162,193,194}

Microbiology and Life Cycle

The oocysts of *C. cayetanensis* found in stool are round, measuring 8 to 10 μm .¹²⁸ In reports from the late 1980s and early 1990s, the taxonomy was in doubt and the organisms were referred to as *Cyanobacterium*-like body, a blue-green algae, a coccidian-like body, *Cryptosporidium*-like, or

big *Cryptosporidium*.^{12,18,74,128,131,132,134,143,161,166} Ortega and colleagues^{128,132} demonstrated sporulation and excystation of the organisms, characterizing them as a coccidian species and suggesting the name *C. cayetanensis*.¹⁹³ Molecular studies have confirmed that the organisms are coccidian parasites closely related to the *Eimeria*.¹⁴¹ Humans are the only known host of *C. cayetanensis*.

Infected patients pass unsporulated oocysts into the environment. A period of 1 to 2 weeks in a warm, moist environment is required for maturation into an infectious, sporulated oocyst.^{164,169} In vivo, excystation of mature sporulated oocysts most likely occurs in the small bowel. In vitro, a combination of bile salts, sodium taurocholate, and mechanical pressure is required for excystation.¹⁶⁹ After excystation, the sporozoites invade the intestinal epithelial cells, where they undergo first asexual and later sexual reproduction. Sexual and asexual stages of *Cyclospora* are found in jejunal biopsy specimens from infected individuals, showing that this coccidian parasite can complete its entire life cycle in a single host.¹³⁰

Epidemiology and Transmission

Cyclospora is found worldwide. Most reports of cyclosporiasis in wealthy countries involve residents of or travelers returning from resource-limited countries.^{72,122,128,132,143,161} The organism has been acquired in numerous geographic areas, including North, Central, and South America; the Caribbean islands; Europe; Turkey; northern, central, and southern Africa; southwest, southern, and eastern Asia; and Papua New Guinea and Australia.^{7,6,22,55,79,110,121,158,164,169,195,196} In one study of diarrheic stool from subjects returning from tropical areas, *C. cayetanensis* was identified in 5% of samples, rendering it the second most common pathogen after *Giardia*.¹⁸⁰ Seasonal variation has been described.^{72,86,128,197} In Nepal, most cases occur during the rainy season, between May and October.⁷² In Peru, the peak is during the fall, between April and June.¹²⁸ The prevalence in endemic regions varies with the age and immunologic status of the host. Prevalence rates in children from Peru and Nepal are reported to range from 2% to 18%.^{72,128} In a Venezuelan review, Chacin-Bonilla and associates³¹ report a prevalence that ranges from 0% to 41.6%. A report from Mexico identified *Cyclospora* in 0.7% of children under age 15.¹²⁷ In Kathmandu, the overall prevalence in children ages 3 to 14 years was 4%, with higher prevalence among 3- to 5-year-olds (10%).²⁰ In one series from Haiti, *Cyclospora* was reported in 11% of adults infected with human immunodeficiency virus (HIV), but was not detected in non-HIV-infected adults or infants younger than 6 months.¹³⁶

Hall and associates⁶⁷ published an active surveillance of *C. cayetanensis* cases in the United States. They noted 370 cases and significant association to travels and outbreaks.⁶⁷

Direct person-to-person transmission is unlikely to occur because a period outside the host is required for maturation into a sporulated oocyst.¹⁶⁹ Contamination of the environment with oocysts plays a major role in the transmission of *Cyclospora*. Foodborne and waterborne transmission of *Cyclospora* have been described.^{65,78,115,169} Waterborne outbreaks have been reported in Chicago and Nepal.^{75,134,193} In one area of Egypt, the average prevalence of *Cyclospora* spores in stool samples was 5.6% in patients with diarrhea, in contrast to 2.3% in asymptomatic subjects, with higher prevalence in places with higher water contamination.⁵⁵ High levels of aquatic contamination also were documented in Hanoi (Vietnam), reaching 63.6% in certain areas, again emphasizing the important role of contaminated water in the spread of the pathogen.¹¹⁴

Foodborne outbreaks have been reported frequently.^{65,69,70,68,78,115} Eleven foodborne outbreaks occurred in North America between 1990 and 2000, affecting 3600 people.¹⁰⁹ For example, widespread outbreaks of cyclosporiasis occurred in the United States and Canada in 1996 and 1997 associated with the consumption of raspberries imported from Guatemala.^{69,70,68} Researchers postulated that the raspberries were contaminated with insecticide or fungicides that were mixed with contaminated water or that the irrigation water was contaminated with *Cyclospora* oocysts.^{133,164} During 1997, clusters of cases were identified in which fresh basil and mesclun lettuce were implicated.¹⁴⁵ Recent multistate outbreaks of cyclosporiasis occurred in the United States, associated with imported fresh cilantro and romaine lettuce.^{1,25} *Cyclospora*

oocysts contaminating vegetables are not removed easily by routine washing.¹³⁰

Clinical Manifestations

Cyclospora affects both immunocompetent and immunocompromised patients.^{79,110,121,128,136,143,161,180,193} The incubation period typically is 2 to 11 days.¹³⁴ In an immunocompetent host, diarrhea may last up to 7 weeks.¹⁹³ Relapsing diarrhea alternating with constipation is the rule.¹⁶⁴ Resolution of symptoms usually correlates with disappearance of the organism from stool.^{72,137} Asymptomatic oocyst shedding also occurs.^{18,143} In one prevalence study in a Venezuelan community, *C. cayetanensis* oocysts were identified in 6.1% of subjects, of whom 84.6% were asymptomatic.³²

In immunocompromised hosts especially onset of watery diarrhea may be abrupt or gradual. Malaise, myalgia, and anorexia are common.^{35,193} Low-grade fever is reported in approximately 25% of patients.^{72,134,161,193} Vomiting may occur but is less common than diarrhea. Other associated symptoms include abdominal cramping, heartburn, and indigestion.¹⁶⁴ Weight loss and malabsorption occur with prolonged illness.^{72,73,165,194}

The median duration of disease in various US outbreaks has been 10 to 20 days (range, 1 to 60 days).⁶⁸ In HIV-infected patients, *Cyclospora* causes symptoms that are indistinguishable from symptoms of *Cryptosporidium* and *Cystoisospora* infection.¹⁹³ Biliary disease was reported in two patients with AIDS who were infected with *Cyclospora*. These patients had clinical and radiographic confirmation of biliary disease and did not have evidence of infection with other pathogens. Both patients had acalculous cholecystitis that was responsive to therapy with trimethoprim-sulfamethoxazole (TMP-SMX).¹⁶⁵ *Cyclospora* also has been identified in respiratory secretions of immunocompromised patients.⁷⁷

Diagnosis

Cyclospora can be visualized by light microscopy on wet mounts or after formal-ether concentration of the stool. In fresh stool, the oocysts are unsporulated. They appear as refractile spherical bodies measuring 8 to 10 μ m and have a central greenish morula that contains six to nine refractile globules.¹³² Safranin staining enhances the outline of the membrane, but does not stain internal structures. Galvan-Diaz and colleagues⁶³ compared safranin and Ziehl-Neelsen stains using as gold standard the direct visualization of the parasite. They found a sensitivity of 95% and specificity of 98% with safranin staining and a sensitivity of 90% and specificity of 100% for Ziehl-Neelsen staining.⁶³

The sensitivity of wet mounts is 75%.¹³⁶ Oocysts exhibit bright blue autofluorescence when exposed to ultraviolet light. Auramine-rhodamine staining enhances the visualization of internal structures. Staining is variable with modified Ziehl-Neelsen stain (Fig. 218.1).¹²⁸ *Cyclospora* is not visualized by Gram, Giemsa, Grocott-Gomori methenamine-silver nitrate, Lugol iodine, periodic acid-Schiff, or hematoxylin and eosin staining.^{138,193}

A direct comparison of formalin-ether sedimentation, direct smear examination, and sucrose centrifugal flotation yielded the highest recovery of *Cyclospora* oocysts in stool with the last method.⁹¹ Nucleic acid tests such as polymerase chain reaction (PCR)^{76,95,97,178,180} and flow cytometry⁵⁴ have been studied as more sensitive detection methods. More recently, multiplex nuclei acid tests, such as FilmArray, have been approved for commercial use with 100% sensitivity and specificity compared to PCR.²⁶

Treatment

When treatment is indicated because of the severity or persistence of symptoms, TMP-SMX is the drug of choice.^{73,105,106,179} No clear alternatives are available in patients who are intolerant of TMP-SMX. Ciprofloxacin was inferior to TMP-SMX in patients with AIDS.¹⁷⁹ Nitazoxanide has been used in a limited number of patients.¹⁹⁸ Prophylaxis with TMP-SMX 3 days per week seems to prevent recurrent episodes in HIV-infected patients.¹³⁶

CYSTOISOSPORIASIS

Cystoisospora belli (previously known as *Isospora belli*) is an intestinal coccidian parasite (Fig. 218.2). Human infection was first recorded in

FIG. 218.1 Oocysts of (A) *Cyclospora cayetanensis* and (B) *Cystoisospora belli* stained with a modified acid-fast stain. Note the variable staining. Note two *Cystoisospora* sporocysts are visible within the shell of one of the oocysts.

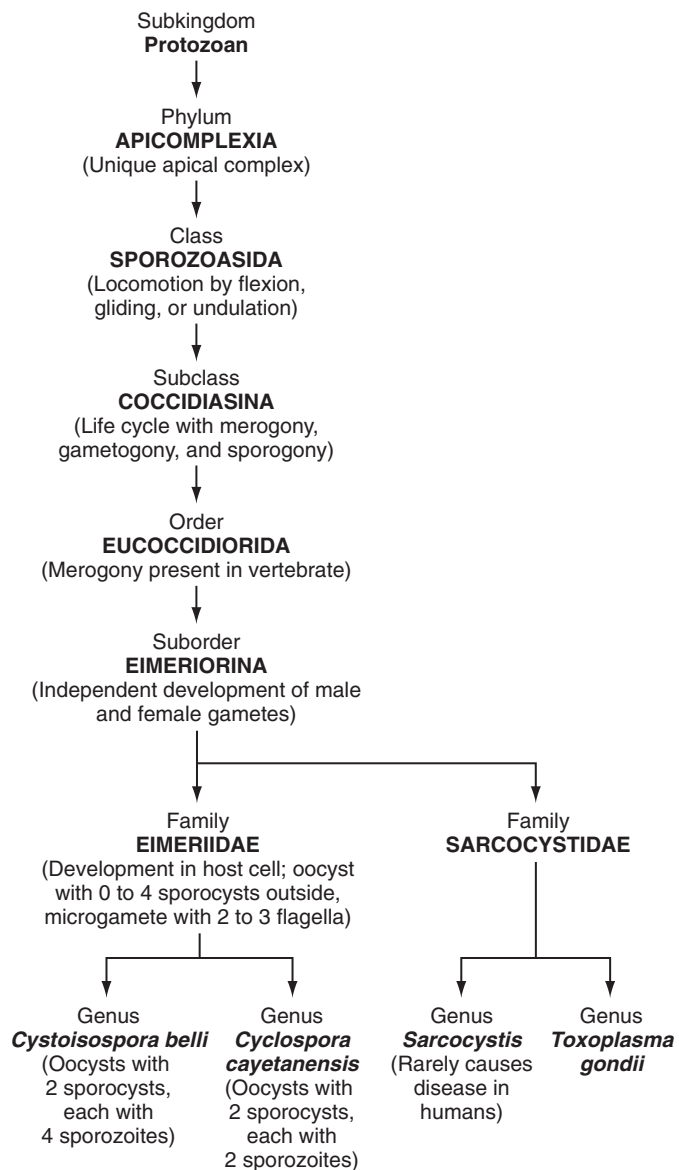

FIG. 218.2 Taxonomic classification of *Cryptosporidium*, *Isospora*, *Cyclospora*, and *Sarcocystis*.

US military personnel during World War I. The first US cases were described in children with chronic diarrhea and malnutrition.²⁴ *C. belli* causes acute and chronic diarrhea in immunocompetent children but can cause prolonged, life-threatening diarrhea and volume depletion in patients with compromised cellular immunity, particularly among patients infected with HIV.^{71,151}

Microbiology and Life Cycle

C. belli is a coccidian parasite.¹⁰¹ The taxonomy was recently revised, separating the genus *Isospora*, with organisms that infect birds reclassified as *Atoxoplasma* and those infecting mammals as *Cystoisospora*.¹⁶ Some species of *Cystoisospora* infect other mammals, but only *C. belli* infects humans.¹⁰¹ Mature oocysts of *C. belli* are oval, measure 10 to 20 $\mu\text{m} \times 20$ to 33 μm , with a translucent thin wall that contains two round sporoblasts, each with four crescent-shaped sporozoites.³⁶ Humans acquire the infection by ingesting food or water contaminated with the mature sporulated oocyst. Excystation occurs in the proximal part of the small intestine, leading to the release of sporozoites that invade enterocytes of the distal duodenum and proximal jejunum and develop into trophozoites. The trophozoites reproduce asexually to form merozoites. The merozoites undergo asexual replication (schizogony or merogony) or sexual replication (gametogony) that results in the production of an immature unsporulated oocyst. This latter form is excreted in stool and requires 12 to 48 hours to mature into the infectious form, a sporulated oocyst.¹⁰¹

Epidemiology and Transmission

C. belli is distributed worldwide, but most cases are reported from tropical and subtropical regions. Travel to or immigration from resource-poor areas is the main risk factor for infection among cases in Europe and North America, including in patients with HIV and AIDS.^{5,66,94,159,167} The incidence of *C. belli* among HIV-infected patients with chronic diarrhea in the developing world varies markedly, with very high rates of 13% to 26% of patients with diarrhea in Venezuela, Haiti, and India.^{2,30,46,182} Infection is also common in Egypt, sub-Saharan Africa, Brazil, and other parts of Asia, but recorded rates have been lower.^{163,186,192} On the other hand, *C. belli* is less common among HIV-infected patients taking cotrimoxazole prophylaxis.^{29,66}

Transmission is by the fecal-oral route. However, direct person-to-person transmission is considered very uncommon, because the immature oocysts shed by humans require at least 1 to 2 days in the environment to become infectious.^{46,101} The incubation period is thought to be 3 to 14 days.¹⁰¹ The infectious dose is largely unknown. The oocysts of *C. belli* are resistant to commonly used disinfectants and may remain viable for months.

Pathophysiology

The pathologic findings are nonspecific. Typical histopathologic findings include shortening of the villi; hypertrophy of the crypts; and infiltration

FIG. 218.3 *Isospora* infecting the jejunum of a patient with severe diarrhea. Trophozoites (*T*) divide within enterocytes by schizogony to form merozoites (*M*). (From Garcia LS, Owen RL, Current VL. Isosporiasis. In: Balows A, Hausler WJ Jr, Ohashi M, Turano A, eds. *The Laboratory Diagnosis of Infectious Diseases: Principles and Practice*. Vol 1. New York: Springer-Verlag, 1988:899-903.)

of the lamina propria with plasma cells, lymphocytes, polymorphonuclear leukocytes, and eosinophils.^{58,120} All stages of the life cycle have been identified within the villous epithelium (Fig. 218.3). *C. belli* also can cause biliary tract infection.¹⁸³ The pathophysiology of cystoisosporiasis has not been defined, but the organisms are strongly associated with diarrhea and malabsorption syndromes.^{10,17,177}

Clinical Manifestations

The main clinical manifestation of cystoisosporiasis is nonbloody, watery diarrhea. However, the spectrum of disease ranges from asymptomatic infection to life-threatening diarrhea. Immunocompetent patients usually have a self-limited illness, although diarrhea may not resolve for several weeks.^{88,116,177} Some children have chronic malabsorption.¹⁷ Headache, malaise, vomiting, fever, and dehydration may be noted. The disease is more severe in infants and children than in adults. In contrast to other protozoan parasites, *C. belli* is strongly associated with peripheral eosinophilia, which can be marked.^{30,85}

The clinical course of cystoisosporiasis in immunosuppressed children depends on their cellular immunity. HIV-infected patients with CD4 cell counts below 200 cells/mm³ are particularly at risk for becoming infected and for presenting symptoms, usually for prolonged periods with intermittent bouts of reactivation.^{10,14,94} Patients who have a reconstituted immune system as a result of effective antiretroviral therapy are seldom symptomatic.¹⁵ Seasonality has been observed in some but not all studies from developing countries.^{30,44} Other conditions associated with depressed cellular immunity, including lymphomas and organ transplantation, predispose to a more severe illness.^{149,150} The onset of illness is insidious and is associated with nonspecific symptoms, such as low-grade fever, headache, malaise, myalgia, and anorexia. Nausea, vomiting, and diffuse abdominal pain may be present as well. The diarrhea is typically watery. Severe dehydration, hypokalemia, metabolic acidosis resulting from bicarbonate losses, and azotemia may occur.^{151,190} Marked weight loss, reaching 30% of body weight, has been reported in a patient with a 9-month clinical course.¹⁵¹ Elevated stool osmolality and steatorrhea are also common findings.

FIG. 218.4 Jejunal biopsy from a patient with AIDS and severe diarrhea. Various developmental stages of the intestinal microsporidian *Enterocytozoon* infect almost every enterocyte. Stages include proliferative plasmodia (1), early sporogonial plasmodia (2), late sporogonial plasmodia (3), and mature spores (4). A spore (arrow) can be seen within a necrotic enterocyte, which appears ready to slough into the lumen. (From Cali A, Owen RL. Intracellular development of *Enterocytozoon*: a unique microsporidian found in the intestine of AIDS patients. *J Protozool*. 1990;37:145.)

Extraintestinal manifestations of *C. belli* are rare; gallbladder and biliary tract infections have been reported in both HIV-infected and immunocompetent patients.^{21,60,183} Cholangitis, defined as elevation of alkaline phosphatase and dilation of the common bile duct detected by ultrasound, was found in 4 of 28 chronically infected patients in France.⁹⁴ The organism has been identified in tracheobronchial, mediastinal, and mesenteric lymph nodes; the spleen; and the liver.¹¹³

Diagnosis

C. belli infection is usually diagnosed by observing oocysts in a stool wet-mount preparation or using modified acid-fast or auramine-rhodamine stain (<http://dpd.cdc.gov/dpdx/Html/Cystoisosporiasis.htm>).^{99,129} Concentration techniques such as zinc sulfate, hypertonic sodium chloride, formalin-ether sedimentation, and Sheather sucrose solution are recommended to increase the sensitivity. Multiple stool samples may be required to make the proper diagnosis. The oocysts are oval, contain one or two sporoblasts, and are 10 times larger than *Cryptosporidium* oocysts. Like *Cyclospora*, the oocysts of *C. belli* exhibit autofluorescence with an ultraviolet epifluorescent illuminator (450- to 490-nm excitation filter). Histologic examination of the small bowel shows nonspecific findings, but asexual and sexual stages of the parasite can be observed within the enterocytes²⁴ (Fig. 218.4). *C. belli* can be found infecting the small and large intestine in patients with HIV and AIDS. Peripheral blood eosinophilia and Charcot-Leyden crystals in stool specimens are present in most cases.³⁷ PCR can increase detection of *C. belli*, and multiplex PCR methods allow for detection of other coccidian parasites at the same time.^{120,173,174} However, these methods are expensive and not widely available.

Treatment

Treatment includes careful attention to fluid replacement, nutritional support, antimicrobial therapy, and, in patients with HIV, antiretroviral therapy. Immunosuppressed patients tend to experience higher degrees of dehydration than immunocompetent patients. In addition, the presence of *C. belli* and other coccidian parasites among HIV and AIDS patients has been associated with higher mortality rates.⁵³ Patients with severe dehydration require intravenous fluids and electrolyte support, with particular consideration to correction of hypokalemia, metabolic acidosis, and children coinfecting with *C. belli* and other coccidian parasites, hypoalbuminemia, and malabsorption of vitamins and fats are commonly described. Hence, careful nutritional support is highly advised in these patients. Patients with mild-to-moderate dehydration who can tolerate the oral route should be offered oral rehydration solutions.

TMP-SMX (TMP 10 mg/kg per day and SMX 50 mg/kg per day in two divided doses, or TMP 160-mg and SMX 800-mg tablet for adolescents twice daily) is the drug of choice.⁹⁹ For immunocompetent hosts, one dose two times per day for 7 to 10 days is curative in most cases.^{46,179} Patients with HIV or AIDS may require higher doses. The current recommendations for these patients are to start with TMP 5 mg/kg and SMX 25 mg/kg two times per day and observe the response, which usually occurs within 2 to 3 days; if no response is observed, the recommendation is to increase the dose to one tablet four times per day for 7 to 10 days. Children who do not respond may have malabsorption of the drug, and, in these patients, parenteral therapy may be considered. Patients with HIV or AIDS present more frequent drug reactions to the sulfa component (SMX) than normal hosts.⁸⁴ Clinical data are very limited on treatment alternatives to TMP-SMX. Ciprofloxacin may have some activity, but it is inferior to TMP-SMX.¹⁷⁹ Pyrimethamine with or without a long-acting sulfonamide is an alternative agent and has worked in some cases refractory to TMP-SMX.^{80,187} Nitazoxanide has in vitro activity, but clinical data are limited to case reports with both successes and failures.^{21,126} Recurrences are very common among patients with HIV or AIDS; therefore, secondary prophylaxis is indicated. Current recommendation includes either TMP 5 mg/kg and SMX 25 mg/kg three times per week or pyrimethamine (25 mg) plus sulfadoxine (500 mg) once a week. Prophylaxis should be continued until the CD4 cell count is out of the AIDS range. However, failure to eradicate *C. belli* even in patients with immune reconstitution has been reported.²³

MICROSPORIDIOSIS

Microsporidiosis comprises a diverse group of infectious diseases caused by the single-cell eukaryotic pathogens from the phylum Microsporidia, formerly termed Microspora.^{52,188,191} Microsporidia were first identified

in 1857 as pathogens of silkworms. The first human infection was described only in 1959, when the organisms were found in the spinal fluid of a Japanese child with seizures. Widespread human infection was initially recognized during the 1980s in AIDS patients. For over a century, the organisms were misclassified as protozoan parasites. However, molecular studies have clarified that the organisms are a unique phylum, closely related to the fungi. Microsporidia have been associated with a wide range of human infections, but most cases present with keratoconjunctivitis or diarrheal disease.

Microbiology and Life Cycle

The phylum Microsporidia includes over 170 genera with more than 1200 species.¹⁸⁸ Eight genera and 14 species have been identified in human infections (Table 218.1). Recent classification schemes reflecting emerging genomic sequences include them with fungi in the Opisthokonta supergroup. All are obligate intracellular pathogens. Their hosts include every animal phylum and some protozoa. Their genomes are highly compact, ranging from 2.3 to 19.5 Mb, with some of the smallest eukaryotic genomes, with few introns, high gene density, and shorter protein sequences than noted for corresponding genes in *Saccharomyces cerevisiae*.^{40,89,140,144} Although the organisms were initially thought to be primitive eukaryotic organisms, recent studies have demonstrated that they are a highly evolved and divergent group of fungal organisms that are highly adapted and specialized for intracellular parasitism. Review of microsporidian genomics indicates that as they adapted to live intracellularly, they have lost genes and now use host proteins for their energy metabolism.^{27,38,56,168} This phenomenon has been associated with increased ability to multiply rapidly within their host.

Microsporidia form characteristic unicellular spores (ranging in size from $1.0 \times 3.0 \mu\text{m}$ to $1.5 \times 4.0 \mu\text{m}$) with a proteinaceous exospore, an endospore made of chitin and protein, and a plasma membrane. All spores contain a nucleus, a polaroplast, and a coiled microtubular extrusion apparatus, termed the polar filament, which is anchored to one end of the spore. The host is infected by ingestion or inhalation of spores. Within the host, the spores undergo extrusion of the polar tube and injection of the sporoplasma into the host cell cytoplasm. Within the host cells, the pathogen undergoes cell division by either binary or multiple fission (merogony). This leads to formation of spores (sporogony), during which meront cell membranes thicken and divide to form spores. The spores are usually released by lysis of the host cell.

Epidemiology

Microsporidiosis has been identified on all continents except Antarctica.¹⁸⁸ Microsporidia infection appears to be common, with mainly asymptomatic or mild self-limited illnesses in normal hosts.^{51,52,108,123,152-154,188} Prevalence is variable and can be as high as 80% in some populations

TABLE 218.1 Microsporidia Implicated in Human Disease

Genus	Species	Main Clinical Manifestation
<i>Enterocytozoon</i>	<i>E. bienersi</i>	Chronic diarrhea
<i>Encephalitozoon</i>	<i>E. intestinalis</i> (syn <i>Septata</i>)	Chronic diarrhea
	<i>E. hellem</i>	Keratoconjunctivitis, disseminated infection
	<i>E. curculi</i>	Disseminated infection, seizure
<i>Trachipleistophora</i>	<i>T. anthropophthera</i>	Disseminated infection
	<i>T. hominis</i>	Myositis
<i>Pleistophora</i>	<i>Pleistophora</i> spp.	Myositis
<i>Anncaliia</i> (syn. <i>Brachiola</i>)	<i>A. vesicularum</i>	Myositis
	<i>A. connori</i>	Disseminated infection
	<i>A. algerae</i>	Keratoconjunctivitis
<i>Nosema</i>	<i>N. ocularum</i>	Keratoconjunctivitis
<i>Vittaforma</i>	<i>V. corneae</i>	Keratoconjunctivitis
<i>Microsporidium</i>	<i>M. africanus</i>	Corneal ulcer
	<i>M. ceylonensis</i>	Corneal ulcer

and not detected in others. Clinical disease was initially recognized in compromised hosts, especially patients with AIDS. Microsporidiosis, especially *Enterocytozoon bieneusi*, are commonly detected in stools from HIV-infected children with persistent diarrhea who are not on effective antiretroviral therapy (up to 77% of cases, but typically about 15%).¹⁷⁶ Microsporidiosis is increasingly recognized in children on immunosuppression for organ transplantation, particularly renal transplant recipients.^{4,62,90,93,96} Among transplant patients, *Enterocytozoon bieneusi* is the most commonly isolated species in stool,^{64,90} but *Encephalitozoon* can cause systemic infection.^{90,147} Recent studies have suggested underdiagnosis in normal hosts, including travelers and children, especially those living in resource-limited countries.^{8,48,102,104,135,155,189} Even a minor increase in economic status can protect against disease.¹²⁵ However, a foodborne outbreak was associated with diarrhea in normal hosts in Sweden.^{45,52}

Most human infections appear to be acquired by ingestion or inoculation in the eye.^{51,52} Sources of ingested organisms include other people, food, and water. Person-to-person transmission was documented in an orphanage.⁹⁸ Pathogenic microsporidial spores are commonly found in surface and drinking water.^{34,61} A foodborne outbreak has been described.³⁵ *Encephalitozoon* species are common in mammals and birds.^{49,48,111,171} *Enterocytozoon bieneusi* has also been reported from pigs and a number of other mammalian and avian hosts.^{49,48,111,156,171}

Clinical Manifestations

Microsporidiosis has been associated with a wide range of clinical manifestations. Most cases present with either diarrhea or keratoconjunctivitis. Less common manifestations include disseminated infection (including neurologic disease) and myositis. Infection of a wide range of other organs has been rarely described, including kidney, liver, central nervous system, and sinuses.

Intestinal and Biliary Tract Microsporidiosis

Human microsporidiosis was first recognized as a cause of chronic diarrhea in patients with AIDS. Most cases of intestinal microsporidiosis are caused by *E. bieneusi* and, less frequently, *Encephalitozoon intestinalis*. Other species have rarely been identified as causes of diarrhea. Cases typically present with severe immunodeficiency (AIDS patients with CD4⁺ cell count <50/mm³ or transplant patients on immunosuppression).^{13,39,56,64,90,92,93,146,176,184,188} AIDS patients typically have chronic diarrhea, often with 3 to 10 loose or watery bowel movements per day. Stools are not typically bloody or mucoid. Affected children also may have anorexia, wasting or failure to thrive, and abdominal pain. Fever is unusual. Intestinal biopsies typically reveal villus atrophy and crypt hyperplasia, and malabsorption of carbohydrates (e.g., D-xylose), zinc, and fats frequently occurs.^{13,100} By contrast, only a limited degree of inflammation is noted.¹⁵⁵ Infection may be fatal without aggressive treatment, but may also be self-limited or asymptomatic, especially in children with higher CD4 cell counts or those on combination antiretroviral therapy.^{19,135} Children with malignancies or who have undergone organ transplantation also may have chronic diarrhea.^{2,4,9,102} In immunocompetent children, most cases are either asymptomatic or self-limited.^{124,152} However, intestinal microsporidiosis has been associated with stunting in some series.^{60,119,142}

Disease may spread to the biliary tract. Biliary tract disease with acalculous cholecystitis and sclerosing cholangitis have been associated with very low CD4 counts.^{60,142} Children have abdominal pain, fever, and right upper quadrant tenderness. Imaging studies may reveal dilation of the intrahepatic and common bile ducts or irregularities of the bile duct and gallbladder wall. AIDS cholangiopathy is similar to cholangiopathy associated with cytomegalovirus and cryptosporidial infection.¹⁶⁴

Ocular Infection

Ocular involvement is also a common manifestation of microsporidiosis. The main manifestations are keratoconjunctivitis and stromal keratitis. Keratoconjunctivitis was initially recognized in patients with AIDS and subsequently in other compromised hosts. However, recent studies from Asia have demonstrated that it is a common and usually self-limited illness.^{42,82,103,148,157,160,175} Most patients have a history of local trauma or

exposure to contaminated water or dirt. Many cases were previously treated with topical steroids. Immunocompetent individuals usually experience a gradual onset in the week before presentation. Most complain of tearing and redness. Other frequent symptoms include the sensation of a foreign body in the eye, ocular pain, and decreased visual acuity. Most cases are unilateral. On examination, all patients have nonpurulent conjunctivitis. Most have a coarse punctate keratitis often accompanied by a superficial scar. Most cases have a full recovery without loss of visual acuity. The clinical presentation of keratoconjunctivitis in AIDS patients and other compromised hosts is more often chronic and bilateral. However, the clinical presentation is still typically with a superficial keratoconjunctivitis.^{160,172,188} Most cases in AIDS patients are thought to be caused by *Encephalitozoon* spp. However, *Anncaliia*, *Nosema*, *Vittaforma*, and *Trachipleistophora* also have been identified in immunocompetent patients with keratoconjunctivitis.

Stromal keratitis often with corneal ulceration is a more severe but less frequent form of ocular microsporidiosis.¹⁶⁰ Stromal keratitis has been described only in hosts thought to be immunocompetent. Cases have been attributed to *Microsporidium* spp., *Vittaforma corneae*, and *Trachipleistophora hominis*. Patients have redness, tears, eye pain, and decreased visual acuity. Cases are often confused with herpetic keratitis. Cure usually requires surgery.

Other Clinical Presentations

Disseminated infection has been described commonly with *Encephalitozoon* spp. Many people are seropositive for *Encephalitozoon* spp., and infection has been associated with seizures, hepatitis, brain abscesses, endocarditis, sinusitis, and respiratory infection.¹⁸⁸ Spores are frequently found in urine, reflecting common involvement of the urinary tract, even in patients with diarrhea. *Pleistophora* spp., *T. hominis*, *Brachiola* spp., *Tubulinosema*, and *Anncaliia* spp. have been associated with myositis.^{28,41,57,139,170,185} Patients present with myalgia, weakness, and elevated muscle enzymes. Cases have been reported in HIV patients with CD4⁺ less than 100/mm³ and patients receiving immunosuppressive therapy for rheumatoid arthritis or solid organ transplants. Anti-tumor necrosis factor agents and corticosteroids have specifically been shown to increase risk.¹⁸⁵

Diagnosis

The mainstay of diagnosis is the demonstration of spores or intracellular organisms in specimens from appropriate tissues.⁵⁶ Stool microscopy remains the most commonly used technique for diagnosis in patients with diarrhea. The spores are similar in size to bacteria and do not readily stain with routine parasitologic stains, so demonstration of the organisms in stool requires special stains. Chromotrope 2R (modified trichrome), Uvitex 2B, calcofluor white, and the quick hot Gram-chromotrope stains have been used to visualize spores in the stool.^{50,112,188} The fluorescent stains (Uvitex 2B and calcofluor white) are more sensitive but less specific than the chromotrope stains. Fluorescent antibody kits are commercially available for identification of *Encephalitozoon* and *E. bieneusi* in water and stool. Urine specimens are frequently positive in cases with *Enterocytozoon* infection.

Organisms are sometimes identified in tissues.¹⁴⁷ Spores can be identified in conjunctival scrapings by Giemsa, Gram-chromotrope, or calcofluor white staining.^{42,83} Tissue Gram stains or chromotrope 2R can be used to stain the organisms in biopsy or autopsy tissues. Occasionally, organisms are identified in intestinal biopsies when missed on stool studies. Electron microscopy can provide more precise anatomic detail but is rarely required.

Molecular assays such as PCR are increasingly being used to diagnose microsporidiosis.^{59,81,148,181} The assays are more sensitive than microscopic methods. Primers are available to identify organisms to the species level.

Treatment

Microsporidiosis diarrhea is usually self-limited in immunocompetent hosts. Thus, when possible, reconstitution of the immune response plays a critical role in management. Children with AIDS should be treated with effective combination antiretroviral therapy, which often will lead to resolution of illness.^{87,107}

Albendazole 400 mg twice daily is effective therapy for some microsporidial species, including a small randomized trial in intestinal infection with *E. intestinalis*.¹¹⁷ It has been used in intestinal and systemic infections.¹⁸⁸ However, albendazole does not work for *E. bienewsi*, the most common cause of intestinal microsporidiosis.¹⁸⁸

Fumagillin is active in vitro against most microsporidial species. A small randomized trial demonstrated efficacy of fumagillin 20 mg three times daily in diarrhea caused by *E. bienewsi*, mainly in AIDS patients.¹¹⁸ There have been recent case reports of successful fumagillin use in the pediatric age group in transplant recipients suffering from *E. bienewsi* diarrhea.^{33,47} Thrombocytopenia frequently occurs during therapy. Fumagillin is licensed in France, but with limited availability. It is not licensed in the United States, but can be obtained for compassionate use.

Keratoconjunctivitis may be self-limited or respond to minor debridement, although debridement alone has not shown any benefits in resolution of corneal lesions or improvement in vision.⁴³ Topical fumagillin is available for ocular use in cases of severe keratoconjunctivitis.⁴² Topical quinolone antibiotics also may be effective. Systemic albendazole may improve some cases and is recommended with *Encephalitozoon* infections, which may be associated with systemic infection. Most patients with stromal keratitis require keratoplasty and may require corneal transplantation.¹⁷²

There have been studies showing progression of myositis to bulbar involvement and dysphagia if not treated aggressively. In places lacking resources to accurately identify Microsporidia species, triple therapy with albendazole, pyrimethamine, and sulfadiazine has been used successfully.¹³⁹

Babesiosis

219

Peter J. Krause

The first reference to babesiosis may have been in the Bible, where a widespread murrain or plague in cattle and other domestic animals is described in Exodus 9:3: “Behold, the hand of the Lord is upon thy cattle which is in the field, upon the horses, upon the asses, upon the camels, upon the oxen, and upon the sheep: there shall be a very grievous murrain.” The word *murrain* has been used to describe red-water fever, a form of babesiosis found in cattle in parts of Ireland.³¹ Babesiosis long has been recognized as an important disease in livestock and has a significant economic impact in many parts of the world; the

health burden of babesiosis on humans has been recognized only more recently.^{31,43,157}

Babesiosis is a disease caused by intraerythrocytic protozoa that are transmitted by ticks from animal reservoirs. Babesiosis has many clinical features similar to those of malaria. The parasite first was described in cattle in 1888 by Babes.⁵ In 1893, it became the first microorganism shown to be transmitted by arthropods when Smith and Kilbourne¹³⁹ identified a tick as the vector for a species of babesiosis (*Babesia bigemina*) in Texas cattle. The first human case was described in 1957.¹³⁶ During

the past 60 years, the epidemiology of the disease has changed from a few isolated cases to the establishment of endemic areas in the north-eastern and northern Midwestern United States and in northeastern China, with reports of cases from a wide geographic range in North America, Europe, Asia, Africa, Australia, and South America.^{63,157} Evidence indicates that the disease is more common in children and adults than is currently reported.^{78,81,157}

EPIDEMIOLOGY

Worldwide, more than 100 species in the genus *Babesia* infect a wide variety of wild and domestic animals. *B. bigemina*, *B. bovis*, *B. divergens*, and *B. major* are found in cattle; *B. equi* is found in horses; *B. canis* is found in dogs; *B. felis* is found in cats; and *B. microti* is found in rodents.⁹⁰ Each species previously was thought to be host specific, but the host range of some species now is recognized to be quite broad.^{56,89,90,143,150} Some confusion has occurred in taxonomy because the identification of different *Babesia* spp. has been based largely on morphology and the vertebrate host.⁵⁴ Most *Babesia* spp. are small (1 to 5 μm in length) and pear-shaped, round, or oval.^{54,89} Several *Babesia* spp. have been found to cause disease in humans, including *B. microti*, *B. divergens*, *B. duncani*, *B. venatorum*, and KO1, as well as several other *Babesia* that are genetically related (e.g., *B. divergens*-like, *B. duncani*-type, *B. microti*-like).^{28,48,59,84,113,134,157} The complete genome of *B. microti* has been sequenced. It has the smallest

nuclear genome of all parasites in the phylum Apicomplexa, including *Plasmodium*, *Toxoplasma*, and *Cryptosporidium*, and has the minimal metabolic requirement for intraerythrocytic protozoan parasitism.²⁹ These and other data suggest that *B. microti* should be renamed, but additional phenotypic and genotypic characterization of this organism and of *B. microti*-like strains or isolates is needed.

Human babesiosis is a zoonotic disease transmitted by a tick vector from an infected animal reservoir (Fig. 219.1). Humans are an uncommon and terminal host for *Babesia* spp., which depend on other species for survival. The primary reservoir for *B. microti* in eastern North America is the white-footed mouse (*Peromyscus leucopus*), but the parasite also has been found in shrews, chipmunks, voles, and rats.^{55,143,151} Two thirds of *P. leucopus* have been found to be parasitemic in endemic areas.¹⁴⁴ *Babesia* spp. are transmitted by hard-bodied (ixodid) ticks. The primary vector in the northeastern United States is *Ixodes scapularis* (also known as *Ixodes dammini*). This same tick transmits five other pathogens: *Borrelia burgdorferi* (the etiologic agent of Lyme disease), *Anaplasma phagocytophilum* (the agent of human granulocytic anaplasmosis), *Borrelia miyamotoi*, Powassan virus, and *Ehrlichia muris*-like agent.^{35,66,70,75,140,142–145,149,158} *I. scapularis* ticks, *P. leucopus* mice, and humans may be infected simultaneously with two or more of these agents.^{95,109,158,7,9,81,84,92,101,152}

Each of the three active stages in the life cycle of *I. scapularis* (i.e., (larva, nymph, and adult) takes a blood meal from a vertebrate host to

FIG. 219.1 Transmission of *Babesia microti* by the *Ixodes scapularis* tick. Adult female ticks lay eggs in the spring (first year, top left panel). Larvae hatch in the early summer and become infected with *B. microti* (red circle) as they take a blood meal from infected white-footed mice (*Peromyscus leucopus*) in late summer. White-footed mice are the primary reservoir host, but other small rodents can carry *B. microti*. Larvae molt to nymphs the next spring (second year, bottom left panel). When infected nymphs feed on mice or humans in late spring or early summer, the hosts may become infected. Humans are accidental hosts, and most cases occur from late spring through summer (row of infected people). In the fall, nymphs molt to adults that feed on white-tailed deer (*Odocoileus virginianus*) but rarely on humans. White-tailed deer do not become infected with *B. microti* but amplify the tick population by providing a blood meal for adult ticks. The next spring, adult female ticks lay eggs that are free of *B. microti* (i.e., no transovarial transmission), and the cycle is repeated. *B. microti* are obligate parasites of erythrocytes. Infection can be detected on Giemsa-stained, thin blood smears (inset). From left to right, the blood smears show a ring form with a nonstaining vacuole surrounded by cytoplasm (blue) and a small nucleus (purple), an amoeboid form, a tetrad (i.e., Maltese cross sign), and an extracellular form. (Modified from Vannier E, Krause PJ. Human babesiosis. *N Engl J Med*. 2012;366:2397–2407.)

mature to the next stage.¹⁴⁴ Ingested babesial organisms infect intestinal tissue of the tick and subsequently travel to the salivary glands, from which they may be introduced into a new vertebrate host.¹¹⁰ *Babesia* spp. are transmitted to the subsequent tick stage (transstadial passage). In some species of *Babesia*, such as *B. bovis*, the organisms may invade the ovaries and pass transovarially to the larvae. The tick transmission cycle begins in late summer, when newly hatched larvae ingest the parasite with a blood meal from an infected rodent and maintain the parasite to the nymphal stage (see Fig. 219.1). Nymphs transmit the *Babesia* spp. to rodents in late spring and summer of the following year.^{144,141} Larvae, nymphs, and adults can feed on humans, but the nymph is the primary vector.¹¹⁰ All active tick stages also feed on the white-tailed deer (*Odocoileus virginianus*), which is an important host for the tick but is not a reservoir for *B. microti*.^{111,144} An increase in the deer population during the past few decades is thought to be a major factor in the spread of *I. scapularis* and the resulting increase in human cases.^{144,141} Domestic animals such as the dog may carry the adult *I. scapularis*, but they do not seem to be important hosts for the tick and are not infected with *B. microti*.^{128,142}

Since the 1980s, human babesiosis has been described with increasing frequency at mainland sites, and studies suggest that the endemic range continues to expand.^{34,37,68,82,157} At certain sites, in years of high transmission, babesiosis may constitute a significant public health burden.⁷⁸ *B. microti* has been identified in rodent populations in several regions of the United States,^{2,3,44,122,143} and human cases have been reported along the East Coast from Maryland to Maine and in Minnesota and Wisconsin (Fig. 219.2).^{20,32,35,37,68,82,99,122,132,146} Moderate to severe illness caused by *B. duncani* and *B. duncani*-type organisms have been reported on the Pacific Coast from northern California to Washington State.^{28,72,107,113} Cases of human babesiosis caused by *B. divergens*-like organisms have been reported in Arkansas, Kentucky, Missouri, and Washington.^{6,57,59,171} The tick vectors and reservoir hosts for *B. duncani* and *B. divergens*-like

organisms have not been definitively identified.^{62,157} In Europe, *B. divergens* and *B. venatorum* infections are transmitted primarily by the cattle tick *Ixodes ricinus*.^{14,42,41,48,63} *B. venatorum* has been found to be endemic in northeastern China, and the likely vector is *Ixodes persulcatus*.⁶⁵ Human babesiosis cases also have been reported in Africa, Australia, and South America.^{16,118,133,134,157,160} An absence of clinical cases of babesiosis in the tropics may be due to cross-immunity from other endemic protozoal diseases.⁶⁹ Most human cases of babesiosis occur in the summer and in areas where the vector tick, rodents, and deer exist in close proximity to humans.^{143,141,146}

Babesiosis also may be acquired through blood transfusion; more than 200 cases have been identified.^{4,13,47,50,51,58,87,88,93,106,137,154,170} *B. microti* is the most common transfusion-transmitted pathogen reported in the United States.^{58,87,170,172} Whole blood, frozen erythrocytes, and platelets have been implicated. The incubation period in these cases is usually 6 to 9 weeks but may be as long as 6 months. Transfusion-transmitted babesiosis has been reported throughout the year and in nonendemic areas. About a fifth of the cases have been fatal.^{58,154,170} Although most cases of babesiosis in neonates have been acquired through blood transfusion, a few cases of transplacental transmission of babesiosis have been described.^{36,39,67,157} The outcome in these cases has been good after treatment with appropriate antibiotic therapy.

PATHOGENESIS AND PATHOLOGY

Understanding of the pathogenesis and pathology of babesiosis in humans is incomplete and is based largely on information gathered from human case studies and studies of babesiosis in other animals. Rudzinska and colleagues studied the life cycle of *B. microti* in erythrocytes using electron microscopy.^{70,120,121} After adhesion and entry into the erythrocyte occurs, the organism multiplies by asexual budding into two to four daughter cells, or merozoites. In contrast to *Plasmodium*

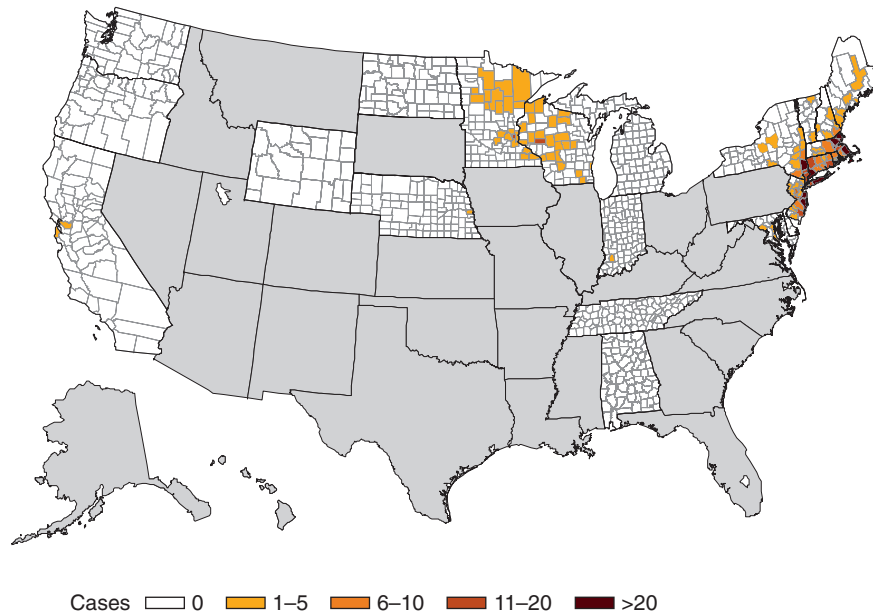

FIG. 219.2 Geographic distribution of human cases of babesiosis in the United States. Babesiosis became a nationally notifiable condition in January 2011. As of 2014, babesiosis was reportable in 22 states and the District of Columbia. The incidence of babesiosis (number of cases per 100,000 people) is shown by county of residence in 2014. Human babesiosis caused by *B. microti* has long been reported from the Northeast, particularly Massachusetts to New Jersey, and it recently became endemic in northern New England (i.e., Maine and New Hampshire) and in the northern mid-Atlantic states (i.e., Pennsylvania to Maryland). *B. microti* also causes disease in the upper Midwest, particularly in Wisconsin and Minnesota. *B. duncani* has been the etiologic agent along the northwest Pacific Coast. Cases of *B. divergens*-like infection have been reported from the states of Arkansas, Kentucky, Missouri, and Washington. (Modified from Centers for Disease Control and Prevention. Surveillance for babesiosis—United States. Available at <http://www.cdc.gov/parasites/babesiosis/data-statistics.html>; and Vannier E, Diuk-Wasser M, Ben Mamoun C, Krause PJ. Babesiosis. *Infect Dis Clin North Am.* 2015;29:357–70.)

spp. merozoites, which are released from the erythrocytes all at once (synchrony), *Babesia* spp. merozoites are released at varying intervals. New erythrocytes are infected, and the cycle is repeated.

The pathogenesis of babesial infection is closely linked to the host response to infection and modification of the erythrocyte membrane.⁷⁴ Investigation of *Babesia rodhoni* suggests that activation of the alternative complement pathway allows entry of the parasite into red blood cells through the C3b receptor.⁶³ It is unknown whether the initial merozoite release leads to destruction of the host erythrocyte, but alteration of the erythrocyte membrane and eventual lysis occur.^{120,147} Erythrocyte lysis is associated with many of the clinical manifestations and complications of the disease, including fever, hemolytic anemia, jaundice, hemoglobinemia, hemoglobinuria, and renal insufficiency. The absence of synchrony decreases the possibility of massive hemolysis and may explain why patients heavily parasitized with *Babesia* spp. may be less ill than patients with *Plasmodium* spp.¹⁴⁷

Babesia spp. are intraerythrocytic protozoa, and extracellular forms are seen only in heavily parasitized cases.^{1,147} *Babesia* organisms do not invade fixed tissue, and evidence in animals suggests that disease results from the excessive production of proinflammatory cytokines (e.g., tumor necrosis factor), as is thought to occur with malaria.^{26,27,74} The release of proinflammatory cytokines in patients with babesiosis may be initiated by contact with an important surface protein, glycosylphosphatidylinositol (GPI).^{24,29} These cytokines subsequently stimulate release of downstream mediators, such as nitric oxide, which kill parasites, but also may cause direct cellular damage if produced in excess.^{23,26}

In addition to proinflammatory cytokine release, obstruction of blood vessels may be caused by adherence of parasitized erythrocytes to vascular endothelium. The accompanying ischemia and necrosis may result in cerebral abnormalities, hepatomegaly and hepatic dysfunction, and splenomegaly.^{31,117,124} Although such cytoadherence appears to occur in cattle infected with *B. bovis*, it has yet to be demonstrated in human babesial infection.^{25,74} A report of fatal human babesiosis with cerebral involvement was not associated with erythrocyte adherence and vascular occlusion.²⁵ Clinical manifestations such as hypotension, vascular congestion, and anoxia also may result from the activation of fibronectin, kallikreins, and complement.^{33,168,167}

Innate and adaptive immune mechanisms limit the severity of babesial infections. The spleen plays a critical role in protection against *Babesia* spp. by removing parasites from infected erythrocytes through a process known as pitting, by ingesting parasites (by means of resident reticuloendothelial cells and macrophages), and by producing antibabesial antibody.^{9,18,30,33,119,157,167} It long has been known that splenectomized animals have more severe babesiosis than animals with intact spleens. Animals that have recovered from babesiosis with negative blood smears have developed parasitemia again after undergoing splenectomy.^{91,129} Many fatal cases of babesiosis in humans have occurred in splenectomized individuals, although asplenia does not always result in death or even severe illness.^{17,119} Other host defense mechanisms that may help limit babesial infection include macrophages and macrophage products, such as tumor necrosis factor,^{26,33,157,167} B lymphocytes,⁹⁸ T lymphocytes,^{18,98,126,164} polymorphonuclear leukocytes,¹³⁵ antibody,¹⁸ and complement.^{9,167}

Age is an important factor in host defense against babesial disease in animals and humans. Most clinically apparent cases are reported in adults, but serologic surveys indicate that children are equally susceptible to infection and presumably are exposed to ticks to the same extent.^{81,128,122} Almost all of the pediatric cases reported have been in neonates.^{39,96,163} Data from a murine model of babesiosis suggested that resistance to *B. microti* infection conferred by the adaptive immune system is genetically determined and associated with age.¹⁵⁵ Immunity is incomplete because parasitemia may exist for months to years in animals and up to 27 months in humans after recovery from the initial illness.⁸⁰ Reinfection may occur, although it is uncommon.

CLINICAL MANIFESTATIONS

Clinical manifestations of babesiosis range from subclinical illness to fulminating disease resulting in death. Overt signs and symptoms begin after an incubation period of 1 to 6 weeks from the beginning of tick feeding or 6 weeks to 6 months after transfusion.^{58,128} The unengorged

I. scapularis nymph is about 2 mm in length, and the patient often has no recollection of having a tick bite. In most cases, the patient has a gradual onset of malaise, anorexia, and fatigue followed by intermittent fever as high as 40°C (104°F) and one or more of the following: chills, sweats, myalgia, arthralgia, nausea, and vomiting.^{1,41,77,84,96,127,122,146} Less commonly noted are emotional lability and depression, hyperesthesia, headache, sore throat, abdominal pain, conjunctival injection, photophobia, weight loss, and nonproductive cough.^{73,124,146,147} In contrast to other tickborne illnesses such as Lyme disease, Rocky Mountain spotted fever, and tularemia, rash seldom is noted.³² Ecchymoses and petechiae have been described.^{71,147}

The findings on physical examination usually are minimal, often consisting only of fever.^{1,59,84,127,146} Mild splenomegaly, hepatomegaly, or both are noted occasionally.^{124,163} Slight pharyngeal erythema, jaundice, and retinopathy with splinter hemorrhages and retinal infarcts also have been reported.^{73,96,104} Several abnormal laboratory findings in patients with babesiosis reflect the invasion and subsequent lysis of erythrocytes by the parasite.^{73,96,124,122} Mild to moderately severe hemolytic anemia occurs, with an elevated reticulocyte count. Elevated liver enzyme levels may be detected in serum.¹²² The leukocyte count is normal, increased, or decreased. Neutropenia may occur.¹⁷³ Thrombocytopenia is common.¹²⁴ The erythrocyte sedimentation rate is elevated. Proteinuria and elevated levels of blood urea nitrogen and creatinine also may be noted.^{71,73,93,124} The illness usually lasts a week to several months, with prolonged recovery taking up to 18 months.^{1,8,80,124,127,146} Parasitemia may continue even after the patient feels well. Persistent parasitemia and relapse of illness, as noted with malaria, has been described 27 months after the initial episode.⁸⁰ Highly immunocompromised patients may experience a prolonged relapsing course of illness despite standard antibiotic therapy.⁷⁶

Some patients, especially patients who are immunocompromised and those with *B. divergens* or *B. duncani* infection, have a more severe form of the disease consisting of fulminant illness lasting approximately 1 week and ending in death or a prolonged convalescence.^{42,52,62,71,72,92,147} Severe *B. microti* illness requiring hospital admission is common in patients with splenectomy; malignancy; HIV infection; chronic heart, lung, or liver disease; organ transplantation; or acquisition of babesiosis through blood transfusion, as well as in newborn infants and the elderly.^{156,157} Signs and symptoms include high fever, hemolytic anemia, hemoglobinemia and hemoglobinuria, jaundice, ecchymoses, petechiae, congestive heart failure, pulmonary edema, renal failure, adult respiratory distress syndrome, and coma.^{45,46,52,71,76,146,147,161} Patients coinfecting with babesiosis and Lyme disease experience more severe acute illness than patients with Lyme disease alone but not patients with babesiosis alone.^{49,84,92,152} Coinfected patients usually experience moderate to severe acute illness, often followed by persistent fatigue. Between 10% and 66% of patients with antibody to *B. burgdorferi* also have antibody to *B. microti*.^{7,81,84}

Inapparent infection occurs in approximately one quarter of adults and one half of children with babesiosis.⁷⁸ Serosurveys provide evidence of asymptomatic infection because of the disparity between seroprevalence rates and the number of indigenous reported cases of babesiosis. In a survey on Nantucket Island in Massachusetts, 2% of 577 random blood samples and 7.5% of 133 blood samples from patients with a history of tick bite or fever had *B. microti* indirect immunofluorescent antibody (IFA) titers of 1:64 or greater.¹²⁷ A survey of adults living on Shelter Island, New York, showed that 6 (4.4%) of 136 study subjects and seven (6.9%) of 102 subjects had *B. microti* IFA titers of 1:64 or greater.³⁸ In a survey of Massachusetts blood donors, 29 (37%) of 779 donors from Cape Cod had *B. microti* IFA titers of 1:16, compared with seven (4.7%) of 148 donors from metropolitan Boston.¹¹² In a serosurvey in Connecticut, 72 (9.5%) of 735 residents who were seropositive for *B. burgdorferi* had positive *B. microti* IFA titers of 1:64, compared with eight (2.7%) of 299 residents who were seronegative for *B. burgdorferi*.⁸² Serosurveys in Mexico, Nigeria, and Taiwan also showed high *B. microti* seroprevalence rates compared with the number of indigenous reported cases of babesiosis.^{60,86,105}

DIAGNOSIS

Specific diagnosis of babesiosis is made by microscopic identification of the organism by Giemsa or Wright staining of thick or thin blood smears and by detection of babesial antibodies by one of several serologic

tests. *Babesia* spp. are round, oval, or pear shaped and have a blue cytoplasm with a red chromatin. The ring form is most common and is similar to the rings of *Plasmodium falciparum*.⁵⁴ *Babesia* spp. can be distinguished from *Plasmodium* spp. by (1) the absence of hemozoin pigment, which is present in older trophozoites of *Plasmodium* spp.; (2) the absence of identifiable gametocytes; (3) the absence of synchronous stages within the erythrocytes; and (4) the presence of the infrequently noted tetrad or Maltese cross form, in which four compact masses, each containing nuclear material, are joined by strands of cytoplasm⁵⁴ (see Fig. 219.1, inset).

Only a few erythrocytes are infected in the early stage of the illness, when most people seek medical attention, so multiple thick and thin blood smears should be examined.⁵⁴ Rapid automated differential blood analyzers may fail to distinguish erythrocytic inclusions.¹⁵ In thick smears, the *Babesia* organism appears as a tiny red-to-purple nucleus with a thin tail of light blue cytoplasm. Maximum erythrocyte infection is approximately 10% in normal hosts but up to 85% in asplenic individuals.¹⁴⁶ Usually less than 1% of erythrocytes are parasitized early in the course of the illness, so the laboratory investigation of possible babesiosis should include more than an examination of blood smears.

If the presence of *Babesia* spp. is suspected but not detected by blood smears, babesial DNA can be amplified and detected using the polymerase chain reaction (PCR).^{83,108,148,159,175} Blood from the patient also can be injected by the intravenous or intraperitoneal route into small laboratory animals such as hamsters or gerbils. If *B. microti* is present in the patient, it usually appears in the blood of the inoculated animal within 2 to 4 weeks.¹⁰ This diagnostic technique is less sensitive and more time-consuming and costly than the PCR.⁸³

Several serologic tests have been developed to detect babesial antibodies, including IFA, ELISA, and Western blot.^{27,79,85,124,131,176} During the acute phase of the illness, titers usually exceed 1:1024, but they decline to 1:64 or less within 8 to 12 months. A babesial IFA titer of 1:1024 or greater usually signifies active or recent infection.^{21,125} Although cross-reactions occur to different *Babesia* spp. and *Plasmodium* spp. with the IFA test, these titers almost always are low ($\leq 1:16$).^{21,22} The problem of cross-reactivity with *Plasmodium* spp. is minimized in areas that have no indigenous malaria. Enzyme-linked immunosorbent assays for detection of *B. divergens* and *B. major* have been found to be superior to complement fixation and IFA procedures.^{11,116,150,153}

PREVENTION AND TREATMENT

The combination of atovaquone plus azithromycin for 7 to 10 days is the recommended therapy for patients with babesiosis. Clindamycin plus quinine is an alternative choice.^{77,174} In patients with severe babesiosis, IV azithromycin plus oral atovaquone should be given; IV clindamycin plus oral quinine is an alternative option.¹⁷⁴ In such patients, exchange transfusion should be considered. The dosage recommendations are as follows^{19,39,45,114,165}:

- Atovaquone—children, 20 mg/kg every 12 hours (maximum of 750 mg per dose); adults, 750 mg orally every 12 hours
- Azithromycin—children, 10 mg/kg given intravenously once a day (maximum 500 mg/dose) or 10 mg/kg once on day 1 (maximum of 500 mg per dose) and 5 mg/kg once per day (maximum of 250 mg per dose) orally thereafter; adults, 500 mg given intravenously once a day or 500 to 1000 mg on day 1 and 250 mg orally once per day thereafter; immunocompromised adults, 600 to 1000 mg/day
- Clindamycin—children, 7 to 10 mg/kg given intravenously or orally every 6 to 8 hours (maximum of 600 mg per dose); adults, 300 to 600 mg every 6 hours intravenously or 600 mg every 8 hours orally
- Quinine—children, 8 mg/kg given orally every 8 hours (maximum of 650 mg per dose); adults, 650 mg every 6 to 8 hours orally

The clindamycin and quinine combination first was used for an 8-week-old infant girl who contracted babesiosis from a blood transfusion.¹⁶³ Initially she was thought to have malaria. Clindamycin and quinine were given after failure with chloroquine. Her favorable outcome suggested the prospective use of this combination in adults. Since then, numerous children and adults have been treated with clindamycin and quinine, with prompt clearing of parasitemia and resolution of clinical signs and symptoms.^{20,19,84,96,146}

The successful use of atovaquone and azithromycin for the treatment of malaria and for babesiosis in hamsters prompted a clinical trial to determine whether the combination would be effective in human babesiosis.^{61,77,162} In the first prospective trial of antibabesial therapy in humans, atovaquone and azithromycin were compared with clindamycin and quinine in adults.⁷⁷ Adverse effects were reported in 15% of subjects who received atovaquone and azithromycin compared with 72% of subjects who received clindamycin and quinine. In approximately one third of subjects taking clindamycin and quinine, the apparent drug reactions were severe enough that the drugs were discontinued or the dosages decreased; this occurred in only 2% of subjects taking atovaquone and azithromycin. Both drug combinations were equally effective in clearing symptoms and parasitemia. Although rare cases of resistance to atovaquone and azithromycin have been reported, this combination is effective in children and adults and is the antimicrobial combination of choice.^{39,114,165,166,174}

Other antimicrobial agents that have been used to treat babesiosis generally are ineffective or found to be useful in only a few cases.⁷⁶ Although chloroquine may give some symptomatic relief of fever and myalgia through its antiinflammatory action, it often fails to clear parasitemia in guinea pigs and humans and is not recommended.^{19,100} Other antimalarial drugs, such as quinacrine, primaquine, pyrimethamine, sulfadiazine, combined pyrimethamine and sulfadiazine, and tetracycline, have no effect on parasitemia in animals. Pentamidine isothionate has been found to decrease fever and parasitemia, but the organisms are not eradicated, and the drug has proved to be ineffective in animals and humans.⁴⁰ Diminazene aceturate was effective in clearing parasitemia and clinical symptoms in one patient, but he developed Guillain-Barré syndrome during recovery, possibly as a result of receiving the drug.¹³⁰ Pentamidine and trimethoprim-sulfamethoxazole were used successfully to treat a case of *B. divergens* infection in France.¹¹⁵

Additional therapeutic measures may be necessary for people with severe babesiosis, especially those who are immunocompromised. Partial or complete red blood cell exchange transfusion is an important adjunctive therapy that can decrease the degree of parasitemia rapidly and remove toxic byproducts of babesial infections.^{17,64,147,157} Exchange transfusion is indicated for patients with severe babesiosis, which is characterized by high-grade parasitemia ($\geq 10\%$), significant hemolysis, or renal, hepatic, or pulmonary compromise.¹⁶⁵ No data are available to determine whether partial or complete exchange transfusion is preferable. For highly immunocompromised patients who experience therapeutic failure with an initial course of standard antibiotic therapy, resolution of infection may require at least 6 weeks of antimicrobial therapy, including 2 weeks after the parasites are no longer detected on blood smears.⁷⁶

Babesiosis can be prevented by avoiding areas where ticks, deer, and mice are known to thrive from May through September. It is especially important for asplenic individuals and other immunocompromised patients who are at increased risk of severe babesiosis and who live or travel in endemic areas to avoid tall grass and brush where ticks may abound. Use of clothing that covers the lower part of the body and that is sprayed or impregnated with diethyltoluamide, dimethyl phthalate, or permethrin (Permanone) is recommended for individuals who travel into the foliage of endemic areas.^{31,138} A search for ticks on people and pets should be carried out and the ticks removed as soon as possible.³¹ Tick removal is accomplished best with tweezers by grasping the mouth parts and gently pulling.^{32,103} Landscape-management approaches such as keeping grass mowed, clearing leaf litter, and spraying property where there is high tick density may help reduce the risk of infection.^{53,94} Reduction of deer on islands has been shown to decrease the number of *I. scapularis* ticks and the incidence of Lyme disease.^{95,138,141,177–179} It is recommended that prospective blood donors who reside in endemic areas and who present with a history of fever within the preceding 1 to 2 months be excluded from giving blood to prevent transfusion-related cases.¹²³ Blood donors who have a history of babesiosis are permanently deferred from donating.^{97,170} Effective *B. bovis* and *B. bigemina* vaccines have been developed for use in cattle, but no *B. microti* vaccine has been developed.^{102,169}

Babesiosis is a worldwide tickborne zoonosis that is endemic in the northeastern and northern midwestern United States and in northeastern China. The incidence is increasing and is greater than

currently recognized. Babesiosis manifests as a viral-like illness with generalized nonspecific symptoms, and diagnosis may be delayed. The diagnosis is confirmed by visualizing the organism on blood smears, or detection of *B. microti* DNA with PCR, or indirectly by detection of *B. microti* antibody. The disease can be severe or fatal, primarily in immunocompromised hosts, but complete recovery with antibabesial chemotherapy is the rule.

Malaria

Rosemary M. Olivero • Elizabeth D. Barnett

Malaria is a disease of global importance. In 2015 there were an estimated 214 million new cases of malaria resulting in 438,000 deaths.¹²² Worldwide, despite declines in malaria cases and deaths, the majority of deaths from malaria continue to occur in children.¹²² Regular transmission of malaria occurs in parts of Africa, Asia, the Middle East, Central and South America, Hispaniola, and Oceania. The infection has been imported by travel to nearly every part of the world. Because of the ubiquity of the infection and the increasing volume of international travel, recognizing the signs and symptoms of malaria and knowing about methods of prevention and treatment are important for health care professionals wherever they practice.^{46,55}

Malaria usually is transmitted from one person to another through bites of infected female *Anopheles* mosquitoes. Disease typically results from infection with one or more of the four species of *Plasmodium* (*Plasmodium falciparum*, *P. vivax*, *P. ovale*, or *P. malariae*) that commonly infect humans. A fifth species, *P. knowlesi*, which is a malaria parasite of monkeys, has also been identified as causing human malaria by zoonotic transmission.²⁹ These protozoa have complex life cycles involving arthropod and vertebrate hosts. If untreated, *P. falciparum* can progress to coma, renal failure, pulmonary edema, and death. Asymptomatic carriage may last decades in the case of infection with *P. malariae*. Relapses are common after infection with *P. vivax* and *P. ovale*. Resistance of the parasites to antimalarial agents and incomplete success in developing and maintaining programs to eradicate the mosquito vectors have contributed to making malaria a persistent worldwide challenge.

HISTORY

Malaria has been known since antiquity and probably affected prehistoric humans. Fossilized mosquitoes have been found in geologic strata 30 million years old. Descriptions of the signs and symptoms of malaria have been found in early Hindu and Chinese writing, and Hippocrates described seasonal and geographic aspects of the disease.¹⁶⁴ Numerous references to malaria occur in literature, ranging from Shakespeare's *The Tempest* to Laura Ingalls Wilder's *Little House on the Prairie*. The name is derived from the Italian *mal aria* ("bad air") based on recognition of the connection between malaria and swamps. One of the first methods of malaria control, draining swamps, was based on this association.

The first malaria treatment known to Europeans was bark of the cinchona tree, which was identified in the early 17th century almost 200 years before the active ingredient (quinine) was isolated. Not until the late 1800s was the vector-borne nature of malaria understood and described; for their roles in this discovery, Laveran, a French military surgeon working in Algeria, and Ross, a British military physician working

in India, were awarded Nobel prizes. Further work by many investigators rounded out the current understanding of the life cycle of the malaria parasites and the complex interrelationship with vector mosquitoes.

During the 20th century, parallel efforts directed toward vector control and discovery and development of drugs to treat malaria were undertaken. The development of larvicides and insecticides permitted control of the mosquito vector. The spectacular success of house spraying with dichlorodiphenyltrichloroethane (DDT) was instrumental in eradicating malaria from most of North America and Europe and in decreasing its prevalence significantly in the Mediterranean area, the Middle East, the Far East, and parts of southern Africa.¹⁴⁵ The development of antimalarial drugs, stimulated largely by the need to protect soldiers during World Wars I and II during shortages of the standard antimalarial agent quinine, allowed for successful treatment of malaria cases.

The World Health Organization (WHO) launched a global campaign for eradication of malaria in 1957. Early successes, attributable to the efficacy of DDT and development of new antimalarial agents, subsequently were hindered by resistance of mosquito vectors to DDT and resistance of the parasites to antimalarial drugs. In 1969, the WHO philosophy on malaria was altered to emphasize the development of health services and research. The goals of malaria control since then have been refined and broadened to include implementation of selective and sustainable preventive measures, early diagnosis and prompt treatment, early detection or prevention of epidemics, and strengthening of local infrastructures to allow better understanding of the determinants of local transmission and malaria control.^{145,164}

During 2000 through 2010, reductions of more than 50% in malaria cases have occurred in almost half (43 of 99) of the countries with ongoing transmission; eight additional countries showed downward trends. These successes are likely due to renewed global commitment to financing of malaria programs, allowing increased access to insecticide-treated mosquito nets (from <2% in 2000 to 55% in 2015 in sub-Saharan Africa), and indoor residual spraying, as well as increased availability of rapid diagnostic tests and artemisinin-based combination therapies.¹²² Reductions in malaria control have proven most challenging in countries with the most intense transmission, such as the Democratic Republic of Congo and Nigeria.¹²² Ongoing challenges to global malaria elimination include maintaining local control measures; resistance to antimalarial drugs, especially to artemisinin derivatives; changes in climate; and population movement as a result of urbanization, mass displacement of populations, and international travel.^{17,86,92,97,122,146}

Mortality from malaria, particularly in adults, increased around the turn of the 21st century, with increases in malaria deaths from 995,000

in 1980 to a peak of 1,817,000 in 2004. Corresponding to the increases in malaria cases attributed to financing of global malaria programs, mortality rates decreased to 1,238,000 in 2010. The majority of malaria deaths continue to be reported from Africa.^{107,122}

Despite reductions in many areas of the world, in the United States in 2011 there were 1925 reported cases of malaria; this represents the highest number of cases since 1980. The number of reported cases declined to 1687 in 2012 then increased to 1727 in 2013.^{32,33} These figures emphasize the impact of international travel on malaria prevalence

in travelers from the United States, and the need for increased prevention measures in this population.

ORGANISM

The life cycle of malaria parasites is complex and requires a suitable population of *Anopheles* mosquitoes and infected humans for completion (Fig. 220.1). To begin the cycle, the female anopheline mosquito injects sporozoites along with saliva in preparation for taking a blood meal

FIG. 220.1 Life cycle of the human malaria parasites. The malaria parasite life cycle involves two hosts. During a blood meal, a malaria-infected female *Anopheles* mosquito inoculates sporozoites into the human host (1). Sporozoites infect liver cells (2) and mature into schizonts (3), which rupture and release merozoites (4). (Of note, in *P. vivax* and *P. ovale* a dormant stage [hypnozoites] can persist in the liver and cause relapses by invading the bloodstream weeks, or even years, later.) After this initial replication in the liver (exo-erythrocytic schizogony [A]), the parasites undergo asexual multiplication in the erythrocytes (erythrocytic schizogony [B]). Merozoites infect red blood cells (5). The ring stage trophozoites mature into schizonts, which rupture, releasing merozoites (6). Some parasites differentiate into sexual erythrocytic stages (gametocytes) (7). Blood stage parasites are responsible for the clinical manifestations of the disease. The gametocytes, male (microgametocytes) and female (macrogametocytes), are ingested by an *Anopheles* mosquito during a blood meal (8). The parasites' multiplication in the mosquito is known as the sporogonic cycle (C). While in the mosquito's stomach, the microgametes penetrate the macrogametes, generating zygotes (9). The zygotes in turn become motile and elongated (ookinetes) (10) and invade the midgut wall of the mosquito, where they develop into oocysts (11). The oocysts grow, rupture, and release sporozoites (12), which make their way to the mosquito's salivary glands. Inoculation of the sporozoites (1) into a new human host perpetuates the malaria life cycle. (From Centers for Disease Control and Prevention. About Malaria: Biology; <http://www.cdc.gov/malaria/about/biology/>)

from a vertebrate host. Sporozoites, the infective stage of *Plasmodium*, remain in the circulation for less than 1 hour and then migrate to the liver, where they invade hepatocytes and multiply asexually. Proliferation within hepatocytes takes approximately 1 week for *P. falciparum* and *P. vivax* and approximately 2 weeks for *P. malariae*. At the end of this period, mature tissue schizonts rupture and release thousands of merozoites, which then invade red blood cells (RBCs). *P. vivax* and *P. ovale* have a second type of exoerythrocytic form, the hypnozoite, which can remain dormant for weeks to years. Dormant hypnozoites may develop weeks, months, or years later into merozoites, which then can enter RBCs and cause relapse of malaria. The factors that influence which exoerythrocytic form develops are not understood. Complete details of the erythrocytic phases of *P. knowlesi* in humans are not yet known.⁸²

Merozoites released from tissue schizonts invade RBCs, where the erythrocytic phase of the life cycle occurs. Two pathways exist in the erythrocytic, or blood, phase: asexual and sexual. In the asexual phase, development of the parasite begins with the youngest stage, the trophozoite or ring form. The parasite undergoes nuclear division to form schizonts and then merozoites in the asexual multiplication process, called erythrocytic schizogony/merogony. Lysis of RBCs releases the merozoites, which invade other RBCs, perpetuating the asexual erythrocytic cycle. The cycle continues until interrupted by treatment or by the host's immune response.

In the sexual phase, subpopulations of merozoites in the erythrocytic phase differentiate into gametocytes, or sexual forms, which then are available for ingestion by mosquitoes to complete the life cycle within the mosquito. Female macrogametocytes and male microgametocytes appear in the circulation within 3 to 15 days of the onset of symptoms. Gametocytes of *P. vivax* may appear in 4 days, whereas gametocytes of *P. falciparum* may require 10 days for development.

In the stomach (midgut) of the mosquito, male gametocyte nuclei divide into four to eight nuclei and form motile gametocytes that fertilize the female gametocytes. The zygotes become motile ookinets that migrate through the wall of the midgut, attach to its outer surface, and form oocysts. The oocysts rupture 9 to 14 days later and release sporozoites that invade the mosquito salivary glands, where they are ready for inoculation into the next vertebrate host.

EPIDEMIOLOGY

Transmission of malaria occurs in large parts of Africa, the Indian subcontinent, Southeast Asia, the Middle East, Oceania, and Central and South America (Fig. 220.2). Although indigenous transmission of malaria has been eradicated almost completely from the United States, Canada, Europe, most of the Caribbean, parts of South America, Israel, Turkmenistan, Morocco, the United Arab Emirates, Armenia, Lebanon, Reunion, Singapore, Hong Kong, Japan, Korea, Taiwan, Brunei, and Australia, many cases of imported malaria occur in these countries each year.¹²²

P. falciparum is the major malaria species in sub-Saharan Africa and the island of Hispaniola, with *P. malariae* assuming a more minor role. *P. vivax* occurs alongside *P. falciparum* in the Indian subcontinent, Central and South America, Mexico, Southeast Asia, and Oceania. *P. ovale* occurs mainly in Africa. *P. vivax* occurs rarely in sub-Saharan Africa because most Africans lack the Duffy blood group antigen necessary for parasite invasion.⁷⁶ *P. knowlesi* has been isolated only in Southeast Asia.¹²²

TRANSMISSION

Epidemiologic Terminology

Patterns of transmission of malaria include stable endemic malaria (natural transmission occurring over many years, with a predictable incidence of illness and prevalence of infection) and unstable malaria (transmission rates vary from year to year in areas of low immunity, with a greater likelihood of epidemics occurring). The degree of endemic malaria is based on the parasite rate in children 2 to 9 years old. Types of endemic malaria include hypoendemic (parasite rate of 0–10%), mesoendemic (parasite rate of 11–50%), hyperendemic (parasite rate consistently >50%, with a high proportion of adults having enlarged spleens), and holoendemic (parasite rate consistently >75%, with a low proportion of adults having enlarged spleens).¹⁶⁴

Autochthonous malaria is acquired locally and may be indigenous or introduced. Introduced malaria may occur when migrant populations with asymptomatic infection provide blood meals for feeding anopheline mosquitoes under conditions that allow for the life cycle to be completed

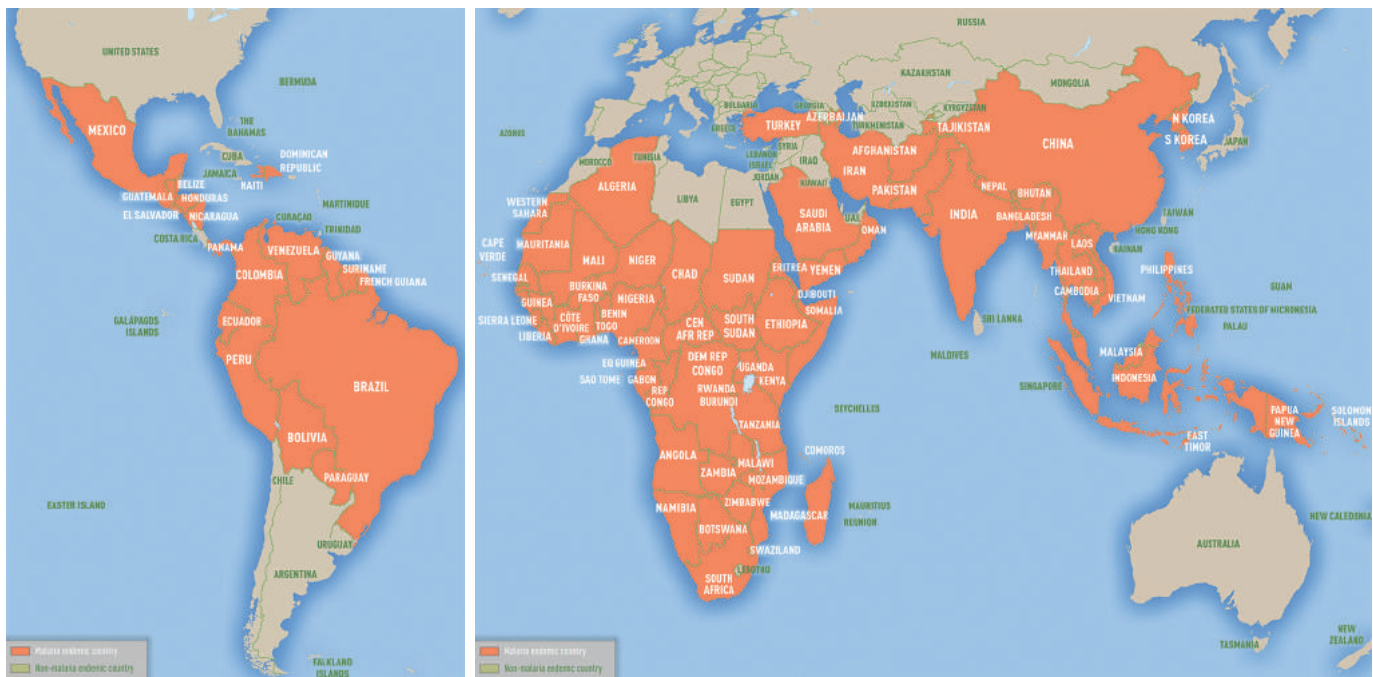

FIG. 220.2 Malaria-endemic countries in the (A) Western and (B) Eastern Hemispheres, 2016. (From Centers for Disease Control and Prevention. *Health Information for International Travel 2016*, <http://wwwnc.cdc.gov/travel/yellowbook/2016/infectious-diseases-related-to-travel/malaria>.)

in the mosquito, enabling the mosquito to infect others. Imported malaria cases may occur in nonendemic areas but result from infection in an endemic area. Induced malaria is acquired by exposure to infected blood, such as from blood transfusion, needlestick injury, laboratory accident, or, historically, medical treatments. Cryptic malaria cases are cases for which no explanation can be found and no epidemiologic link to other cases can be identified.

Mosquito-borne Transmission

The most typical means of transmission of malaria is through the bite of an infected female anopheline mosquito. Although more than 450 species of *Anopheles* mosquitoes exist, only approximately 60 have been shown to be effective vectors of malaria.²⁵ A population of infected humans is necessary to sustain transmission because of the short life span of mosquitoes (5–20 days) and the long incubation period required in the mosquito (8 to ≥ 10 days).

Bloodborne Transmission

Transmission of malaria via blood transfusion is well documented.^{106,123} Transmission also may occur through organ donation or needlestick injury.^{32,57} Relapses of malaria cannot occur with bloodborne transmission, even if the infecting species is *P. vivax* or *P. ovale*, because the infection is produced by the transmission of infected RBCs rather than by forms that invade the liver.

Congenital Malaria

Infants can acquire malaria from their mothers during pregnancy. Transplacental transmission of parasites has been proposed as the most likely route of transmission, although breakdown of placental barriers allowing transmission of maternal blood cells to the infant during labor or delivery also has been suggested as a mechanism of transmission.^{64,94,102} *P. vivax* most often is associated with this phenomenon, but it may occur with all species. Congenital malaria is less likely to occur in infants of semi-immune mothers because of transplacental passage of maternal antibody during the third trimester. As with transfusion-associated malaria, relapses do not occur. An important sequela of infection that occurs in pregnancy is fetal growth restriction and increased risk of morbidity and mortality.¹⁶⁹

Cryptic Malaria

The category of cryptic malaria includes cases for which no source of infection can be identified. Typical cases include confirmed malaria in US residents who have never traveled to or resided in malarial areas, who have not received blood transfusions, and who are not linked epidemiologically with other cases.^{32,81,136} Airport malaria, one kind of cryptic malaria, occurs in proximity to international airports and is thought to occur when mosquitoes arriving with airplanes from endemic areas infect individuals working in or living near airports.⁷⁵

HOST-PARASITE INTERACTION

The intensity of transmission of malaria depends on factors that affect the density of vectors and the extent of vector-human contact. Transmission of malaria may be continuous or seasonal, or it may depend on local site-specific factors, such as the presence of irrigation projects or intermittent flooding. Mosquito vectors differ in their efficiency in transmitting malaria; the principal vector in sub-Saharan Africa, *Anopheles gambiae*, is known for being a highly effective vector. Variations in climate may affect the viability of mosquitoes.

The incidence and severity of malaria are affected by the intensity of exposure, the presence of immunity, and genetic factors. Distinction must be made between malaria infection (presence of parasitemia) and malaria illness. A major puzzle in malaria is why individuals with similar degrees of parasitemia may exhibit radically different clinical manifestations.

Individuals who reside in endemic areas and are exposed continually to infected mosquitoes acquire some degree of immunity to malaria illness. Adults in these areas continue to become infected, but they have lower levels of parasitemia. Infants born to mothers with acquired immunity may be protected transiently by transplacental passage of

maternal antibody. The highest incidence of infection with malaria occurs in infants and young children who are no longer protected by maternal antibody but who are too young to develop sufficient acquired immunity. The lack of acquired immunity in infants and young children accounts partly for their increased risk for acquiring disease and having severe manifestations such as cerebral malaria. Acquired immunity diminishes during pregnancy, and pregnant women are at high risk for development of severe complications of malaria. Individuals in the population who remain asymptomatic but harbor gametocytes in their blood are reservoirs of infection when bitten by mosquitoes. With the exception of *P. knowlesi*, which infects monkeys, there are no significant animal reservoirs of malaria.

Clinical manifestations of malaria may be severe in nonimmune patients. Malaria is the most common life-threatening infection acquired by travelers to malaria-endemic regions. Individuals with acquired immunity who then leave endemic areas for long periods may lose their immunity and be at risk for severe disease if reexposed.

Genetic factors determine the risk for acquiring malaria and having severe infection. Individuals who have a Duffy-negative blood type lack the most important specific receptors for invasion of the merozoites of *P. vivax*, and these individuals have markedly reduced susceptibility to infection with this species.^{76,103} This resistance is the basis for the low incidence of vivax malaria in Africa. Specific human leukocyte antigens present in individuals from West Africa may protect against the development of severe complications of malaria, including cerebral malaria and severe anemia. The best-known example of the relationship between malaria and genetics is the association between sickle hemoglobinopathies and protection against severe falciparum malaria. This balanced polymorphism is thought to have helped ensure survival of the gene for hemoglobin S in the population because of the selective advantage provided on a population basis to those who are heterozygous for sickle-cell disease. Individuals with sickle hemoglobinopathies still may be infected and manifest signs and symptoms of malaria, although the risk for acquiring severe malaria or dying of malaria may be 60-fold to 70-fold less in children with hemoglobin AS than in children with hemoglobin AA.¹⁶⁸

PATHOPHYSIOLOGY

Pathophysiologic changes in malaria are caused by destruction of RBCs, production of cytokines, stimulation of intravascular synthesis of nitric oxide, and sequestration of infected erythrocytes.

Lysis of RBCs leads to anemia, which may be acute and severe, and its attendant hemodynamic consequences. Anemia may develop as a result of hemolysis, impaired erythropoiesis, or bone marrow depression secondary to folic acid deficiency.¹²⁷ Intravascular hemolysis may be so severe that it results in pronounced hemoglobinuria (blackwater fever), which may be a precipitating event in the development of renal failure. This complication has been noted in association with treatment using quinine. Hematopoiesis is suppressed during acute infection, and such suppression may not be reversed as readily in iron-deficient individuals, contributing to the development of chronic anemia.

Cytokines such as tumor necrosis factor (TNF) and interleukin-1 have important roles in the pathogenesis and severity of malaria infection.^{14,77,79} Severe disease has been associated with higher concentrations of TNF, and TNF polymorphisms may play a role in the development of specific complications.^{99,100} Higher TNF concentrations have been observed in those with cerebral malaria and those who have required longer hospitalizations for malaria.⁷⁷ Parasite factors responsible for release of cytokines have not been identified. A possible mechanism for the role of TNF in malaria pathogenesis is the binding of TNF to its receptors, causing signaling to amplify cytokines of inflammatory cascades.¹³⁸ Another possible role of TNF in malaria is to stimulate production of nitric oxide, a short-lived neurotransmitter. Nitric oxide may have a role in cerebral malaria pathogenesis, and its transient nature may provide a partial explanation for the complete recovery noted in some patients with severe cerebral malaria. TNF and nitric oxide have both harmful and beneficial roles in the pathogenesis of malaria; both have been shown to be correlated with clearance of parasites and eventual recovery and with severity of illness.

Sequestration of infected RBCs has long been thought to contribute to the clinical manifestations of malaria, particularly that caused by *P. falciparum*. Late-stage parasites induce host cells to develop knobs on the surface of erythrocytes that facilitate adherence of these cells to vascular endothelium. The effects of these sequestered RBCs on the perfusion, nutrition, and oxygenation of surrounding tissues may be responsible for the complications of *P. falciparum* infection, including cerebral malaria, renal failure, and watery diarrhea.^{109,132} Consumption of glucose by metabolically active late-stage parasites contributes to hypoglycemia and lactic acidosis. Despite these changes, the majority of histopathologic appearances of tissue is remarkably benign, consistent with the reversible nature of the changes and supportive of the role of cytokines and secondary messengers in the pathogenesis of complications of cerebral malaria.^{164,168} Recent postmortem microscopy of brain sections from adults who died of malaria confirmed that sequestration of cerebral microvasculature was significantly higher in patients with cerebral malaria and was also correlated with deeper levels of premortem coma and shorter time to death.¹³³

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

The clinical manifestations of malaria depend on the species causing the infection, the immune status of the individual, the mode of transmission of infection, whether the individual was taking prophylaxis, and host immune factors (Table 220.1). Acute malaria generally is understood to refer to the signs and symptoms associated with disease caused by infection with malaria parasites.

Recurrent infections are of three types: relapse, recrudescence, and reinfection. Relapses occur as a result of delayed maturation of the dormant liver stages (hypnozoites) of *P. vivax* or *P. ovale*. Recrudescence occurs when parasitemia caused by the same parasite responsible for the initial infection recurs after clearance or a significant reduction in the initial parasitemia, and occurs most commonly with *P. falciparum* because of drug resistance. Reinfection with different parasites and infection with more than one type of *Plasmodium* occur especially in areas with a high intensity of transmission. Persistent infection is noted with *P. malariae*; hypnozoites have not been identified with *P. malariae*, so the organism is thought to persist as a low-level parasitemia that can exist for years without causing symptoms.

A classic description of malaria includes features of the malaria paroxysm resulting from lysis of parasitized RBCs and release of merozoites into the circulation at the completion of asexual reproduction. The paroxysm is characterized by fever and chills accompanied by constitutional symptoms of headache, body ache, fatigue, dizziness, and malaise. Gastrointestinal symptoms include nausea and vomiting, abdominal pain, and diarrhea. Cough and dyspnea may accompany an attack. Although periodicity of the paroxysms in primary attacks is thought to be pathognomonic for malaria species, this periodicity may

take several days to become established, may not occur at all in asynchronous infections, or may be modified by previous immunity or treatment.

In children, fever and headache may be the sole symptoms or gastrointestinal symptoms may predominate. Physical signs of malaria include pallor, jaundice, and hepatosplenomegaly. Rash and lymphadenopathy typically are not associated with malaria, although malaria may precipitate recrudescence of latent herpes infections.

Anemia is the most common laboratory abnormality in malaria. Thrombocytopenia is common and may be the first manifestation in patients with uncomplicated malaria.¹⁶⁸ Leukopenia also may occur, and leukocytosis is less common and should provoke investigation for other conditions. Liver function test abnormalities may be present and can be mistaken for infectious hepatitis, especially in patients with jaundice and tender hepatosplenomegaly. Hypoglycemia occurs frequently with falciparum malaria and may develop before or as a consequence of treatment with quinine. When present in children before treatment, hypoglycemia is associated with a poor prognosis.¹⁶⁵ Hyponatremia may occur as part of the syndrome of inappropriate secretion of antidiuretic hormone. Serum creatinine and blood urea nitrogen values may be elevated transiently or may increase significantly with acute renal failure.

Malaria stimulates a polyclonal increase in immunoglobulins associated with rapid production of malaria-specific antibodies and reduced complement levels. False-positive tests for syphilis, rheumatoid factor, heterophil agglutinins, and cold agglutinins may occur.¹⁶⁴

Severe and Complicated Malaria

Nonimmune individuals are most susceptible to severe complications of falciparum malaria, which include cerebral malaria, pulmonary failure or acute respiratory distress syndrome, renal failure, and severe anemia.⁹⁰ Hypoglycemia and metabolic acidosis may occur. Falciparum malaria in nonimmune patients should be considered a medical emergency, and treatment of *P. falciparum* should be initiated in all ill patients with malaria until the species can be confirmed. The highest mortality is seen in those who have a combination of severe respiratory distress, impaired consciousness, and severe anemia. The Centers for Disease Control and Prevention (CDC) and WHO criteria for the diagnosis of severe malaria are outlined in Table 220.2.

Severe Anemia

Children younger than 1 year old, especially in sub-Saharan Africa, are those most likely to experience severe malarial anemia. This complication is thought to occur most often in areas with year-round transmission. Clinical consequences of anemia are determined by rate of development and severity of the anemia, with high risk for complications as hemoglobin decreases to less than 5 g/dL.¹¹² Hemolysis has been reported as a consequence of treatment with artemisinin derivatives, most commonly IV artesunate, approximately 2 weeks after initiation of treatment¹⁴²; it

TABLE 220.1 Characteristics of the <i>Plasmodium</i> Species Responsible for Human Malaria					
Characteristic	SPECIES				
	<i>P. falciparum</i>	<i>P. vivax</i>	<i>P. ovale</i>	<i>P. malariae</i>	<i>P. knowlesi</i>
Incubation period in days (range)	12 (8–25)	14 (8–27)	17 (15 to ≥18)	28 (15 to ≥40)	11 (9 to >12)
Periodicity of febrile attacks (hours)	None	48	48	72	24

TABLE 220.2 Manifestations of Severe Malaria

Centers for Disease Control and Prevention Definition ^a	World Health Organization Definition ¹⁶²
Cerebral malaria	Prostration, impaired consciousness, coma
Severe anemia	(cerebral malaria) or multiple convulsions
Acute renal failure	Severe anemia
Hemoglobinuria	Renal impairment
Hypoglycemia	Hemoglobinuria
Metabolic acidosis	Hypoglycemia (<40 mg/dL)
Hypotension caused by cardiovascular collapse	Acidosis or hyperlactatemia
Acute respiratory distress syndrome	Circulatory collapse or shock
Coagulopathy	Respiratory distress or pulmonary edema
Hyperparasitemia (>5% infected RBCs)	Abnormal bleeding
	Hyperparasitemia (>2% infected RBCs in low-transmission areas or >5% in high-transmission areas)
	Jaundice
	Failure to feed

RBCs, Red blood cells.

^aFrom www.cdc.gov/malaria/about/disease/html/severe.

is unclear whether this hemolysis is a complication of artemisinin treatment rather than the severity of malaria in these cases.

Hypoglycemia

Hypoglycemia (blood glucose <40 mg/dL) may be present on initial evaluation in 20% of children with severe malaria and is associated with a poor prognosis. The etiology of pretreatment hypoglycemia is thought to be a combination of parasite consumption of glucose and inadequate gluconeogenesis in the liver. Hypoglycemia also can occur as a result of treatment, most typically with quinine. Intravenous or oral administration of quinine may lead to hypoglycemia by stimulating insulin secretion. Pregnant women seem to be especially susceptible to this complication.

Acid-Base Changes

Metabolic acidosis is a marker of malaria illness severity and clinically may manifest as hyperpnea. Acidosis often is associated with hypoglycemia. Fluid resuscitation and treatment with antimalarial drugs often result in rapid resolution of acidosis, although persistence of acidosis may occur in patients who eventually die of malaria.

Renal Complications

Acute renal failure is a potentially life-threatening consequence of acute malaria that occurs more commonly in adults than in children. It typically is oliguric and often is reversible if the patient can be supported by dialysis through the oliguric phase. Acute renal failure is a rare development in residents of endemic areas and long has been thought to occur more frequently in patients treated with quinine or quinidine (blackwater fever). The histologic changes resemble those of acute tubular necrosis.

Nephrotic syndrome and chronic renal failure occur more frequently in areas where malaria is endemic and usually are associated with infection with *P. malariae*. Symptoms occur in individuals younger than 15 years old in approximately half of cases, with gradual progression to renal failure over 3 to 5 years. Most patients have asymptomatic proteinuria and the gradual development of hypertension and deterioration in renal function. Adults more commonly have hematuria and azotemia; adults and children may have hematuria. The disease does not respond to antimalarial agents. Treatment with corticosteroids, cyclophosphamide, and azathioprine has had variable results, with remission occurring only in patients with mild changes on renal biopsy.¹⁶⁴

Respiratory Complications

Pulmonary edema typically develops late in the course of severe malaria when other complications are already present, and it may occur when parasitemia has resolved and the patient appears to be improving clinically. Pulmonary edema occurs more commonly in adults than in children, and the pathogenesis is consistent with capillary leak syndrome. Supplemental oxygen or mechanical ventilation with positive end-expiratory pressure may be necessary to manage respiratory complications. A well-characterized pulmonary inflammatory response driven by alveolar macrophages can lead to respiratory distress in severe malaria.¹¹⁸ Respiratory distress is the most dangerous presentation of severe malaria, especially in combination with severe anemia and cerebral malaria.⁵²

Cerebral Malaria

Cerebral malaria is the most common complication of falciparum malaria in children and occurs most often in children 3 to 6 years old.^{66,128} It presents as alteration of consciousness and diffuse encephalopathy with prolonged multiple seizures in a patient with no other explanation. Patients may be comatose without response to stimuli and may assume an opisthotonic posture. Generalized convulsions may occur, and focal findings are uncommon. Serial electroencephalographic monitoring of 65 Kenyan children uncovered a large range of clinical and electrographic seizures with diffuse background slow-wave activity, which are nonspecific features; electrical seizure activity consistently arose from the posterior temporoparietal region.³⁰ Intracranial pressure often is increased in children with cerebral malaria, and the presence of increased intracranial pressure was recently found to be associated with increased mortality.¹⁵² Factors associated with neurologic sequelae include prolonged coma, severe anemia, and multiple seizures. Mortality rates range from 15% to 30% of affected children; most survivors recover completely, though approximately 10% may have neurologic sequelae. The most common neurologic sequelae in children noted in a study in the Gambia were hemiplegia, cortical blindness, aphasia, and ataxia.¹⁹

Many factors, including hypoglycemia, anemia, microvascular obstruction, acidosis, and elaboration of inflammatory mediators, contribute to the syndrome of cerebral malaria. Histopathologic features are minor, with occasional hemorrhages and perivascular infiltrates.

Malarial retinopathy is a more recently described phenomenon in children with falciparum cerebral malaria. The retinal changes seen in malarial retinopathy include retinal whitening, vessel discoloration, retinal hemorrhages, and papilledema, and the severity of retinal findings has been found to have prognostic value in predicting risk of death and length of coma in survivors of severe malaria.¹²

Hyperreactive Malarial Syndrome (Tropical Splenomegaly Syndrome, Hyperreactive Malarial Splenomegaly)

Hyperreactive malarial syndrome is characterized by massive splenomegaly, high concentrations of total serum IgM and malarial antibodies of multiple immunoglobulin classes, and clinical and immunologic response to antimalarial agents.^{84,183} Hyperreactive malarial syndrome is correlated with malaria endemicity, with an incidence ranging from 0.5% to 80% of the adult population. The pathogenesis is unknown but seems to involve chronic exposure to malaria, resulting in chronic stimulation of the immune system and genetic factors. Findings on physical examination include a huge spleen (>10 cm below the costal margin) and an enlarged liver. Laboratory findings include anemia and an increased reticulocyte count, elevated IgM (>2 standard deviations above the mean), and high antibody levels of antimalarial antibodies.¹⁵⁷ Some patients have thrombocytopenia or neutropenia. Patients may have an increased risk for acquiring bacterial infections, and some researchers have suggested that hyperreactive malarial syndrome is a premalignant condition.¹⁰ Lifelong treatment with antimalarial agents is the treatment of choice for patients who reside in endemic areas.⁸⁴ Treatment of patients who have left endemic areas has not been standardized; several case reports show success with a single short (<7 days) treatment course of antimalarial agents followed by close monitoring of the size of the spleen.^{84,157}

Malaria in Special Populations

Malaria in Children

The signs and symptoms of malaria in children range from asymptomatic infection to life-threatening illness. Severe anemia is most likely to develop in children younger than 2 years old, whereas cerebral malaria is most likely to occur in older children (mean age, 3.5 years). The greatest burden of disease is borne by infants and young children, although the impact of disease on adolescents has not been studied extensively. Malaria in pregnant adolescents may be of particular concern.⁸⁰

In endemic areas, lack of diagnostic facilities, limited resources, and encroaching drug resistance complicate the ability to make a rapid, accurate diagnosis and provide expedient treatment to children with malaria. Malaria often is difficult to distinguish from other common illnesses such as pneumonia. Clinical algorithms that can distinguish children with malaria from children with pneumonia or other illnesses have been developed and studied but do not eliminate completely the overlap with conditions having similar clinical manifestations.^{139,140,148} Risk factors for a fatal outcome in children with malaria were studied in Kenya; the presence of coma or respiratory distress, or both, at initial evaluation identified children at high risk for dying.^{52,96}

Imported malaria occurs in children in many nonendemic countries. The diagnosis often is delayed because of lack of consideration of malaria as a cause of illness and unfamiliarity with the disease. In children with acquired immunity, the signs and symptoms of disease may be subtle and nonspecific, but fever or a history of fever is universal.^{40,89} Other symptoms include anorexia, vomiting, diarrhea, headache, lethargy, and abdominal pain. Laboratory findings include anemia, thrombocytopenia, and leukopenia. The diagnosis of malaria should be considered in every child with fever or a history of recent fever who has visited an area where malaria occurs.

Congenital Malaria

P. falciparum, *P. malariae*, *P. vivax*, and *P. ovale* can be transmitted congenitally, but the disease most often is associated with *P. vivax*. Congenital malaria has not been reported with *P. knowlesi*. That congenital malaria is not seen more frequently is due partly to the effective barrier function of the placenta. Congenital malaria develops in infants of approximately 0.1% of immune mothers and 10% of nonimmune mothers in endemic areas, although placental infection occurs in one third of pregnant women.⁷⁰ In endemic areas, distinguishing malaria acquired congenitally from malaria acquired by transmission from mosquitoes is difficult. In non-malaria-endemic countries, congenital malaria is very rare; only five cases have been reported in the United States since 2000.²⁷

The onset of symptoms is insidious and usually occurs at 2 to 8 weeks of age. The typical malaria paroxysm is absent, with the infant instead having poor feeding, fever, vomiting, diarrhea, irritability, and hepatosplenomegaly on physical examination.⁶⁴ The most common laboratory finding is anemia, but thrombocytopenia and hyperbilirubinemia also occur. Therapy for the infecting species of malaria is curative, and the infant does not need treatment of the exoerythrocytic stages of the parasite (although the mother does).

Malaria in Pregnancy

The effects of malaria on the mother depend on the degree of immunity that she has attained and her parity.¹⁰² Relapses and recrudescence of malaria are common during pregnancy, as acquired immunity diminishes with the pregnant state. Malaria can exacerbate the anemia occurring during pregnancy, and hypoglycemia and renal insufficiency may complicate falciparum malaria during pregnancy.⁵¹

Placental infection during pregnancy is associated with delivering low-birth-weight infants, particularly in primigravidas. Fetal growth restriction begins early in gestation and can occur even in asymptomatic parasitemia.¹⁴⁴ An in vitro study showed that placental falciparum malaria results in inhibition of transplacental amino acid transport and that this is a plausible mechanism of fetal growth restriction.¹⁵ Vivax malaria has been linked to maternal anemia and low birth weight in multigravidas and primigravidas.¹¹³ Severe falciparum malaria is harmful to the fetus

because of fetal tachycardia and distress secondary to maternal fever; disruption of maternal-fetal blood flow and exchange of metabolic substrates by malaria parasites trapped in the placenta; and the potential for reduction in fetal glucose supply, which may be exacerbated by treatment with quinine, a drug that is able to stimulate the release of insulin.⁸⁸ Heavy infection of the placenta interferes with transfer of tetanus antibodies from the mother to the fetus, but the effect on other antibodies is unknown.¹⁸ Prompt treatment of pregnant women with malaria is critical to survival of the mother and the fetus, as fetal growth restriction and low birth weight are associated with high infant mortality and morbidity rates.^{15,169}

DIAGNOSIS

The most important first step in establishing the diagnosis of malaria is to consider the diagnosis in all individuals with febrile illness, especially febrile individuals with a history of travel to endemic areas. Having a high index of suspicion for the diagnosis of malaria cannot be over-emphasized. Failure to diagnose and treat malaria promptly contributed to fatal outcomes in US civilians who died of malaria between 1963 and 2001.¹¹¹ In one series of fatal falciparum malaria cases in the United States, 40% of patients were not recognized as having malaria during their initial contact with a physician.⁵⁰ Manifestations of the disease are most classic in nonimmune individuals or in individuals in areas where malaria transmission is seasonal. Signs and symptoms of disease may be nonspecific in semi-immune individuals, those who have received malaria prophylaxis, or individuals who have been partially treated.

In nonendemic areas, a history of travel to an endemic area should suggest the diagnosis in all individuals with a febrile illness, regardless of the accompanying signs and symptoms.¹⁷⁹ Common diagnoses mistakenly assigned to patients ultimately determined to have malaria include gastroenteritis and viral syndrome. The course of disease may be modified by exposure to antimalarial drugs, such as agents that may have been used for prophylaxis, and the incubation period may be prolonged after the administration of antimalarial chemoprophylaxis. Because malaria may be transmitted by blood transfusion or an organ transplant, may be congenitally acquired, and, rarely, occurs cryptically, the diagnosis also should be considered in patients with compatible signs and symptoms of malaria, anemia, or thrombocytopenia and no other explanation for their illness.

Microscopy is the technique traditionally used for establishing the diagnosis of malaria. Rapid diagnostic tests to detect parasite antigens are important tools in centers lacking around-the-clock expertise in malaria diagnostic microscopy. Other alternatives to microscopic diagnostic techniques for malaria include tests using fluorescent microscopy, DNA probes, polymerase chain reaction (PCR), antibody detection, and flow cytometry. Only a few of these methods meet the requirements of low cost, high reliability and reproducibility, and rapid turnaround time. Some of them are suitable for use in field conditions, however, and have been used in endemic areas and for self-diagnosis.

Diagnosis of cerebral malaria is largely clinical. Patients with cerebral malaria typically do not have marked cerebrospinal fluid (CSF) pleocytosis, differentiating this entity from bacterial meningitis. In comparing CSF parameters in children with cerebral malaria to those with viral encephalitis, those with cerebral malaria have a lower CSF glucose level and higher protein and lactate dehydrogenase (LDH) levels, CSF-to-blood LDH ratio, and CSF-to-serum adenosine deaminase ratio.⁶⁸ The clinical finding of malarial retinopathy shows promise in aiding in the diagnosis of severe falciparum malaria complicated by coma,¹² but use of this finding is limited to settings where indirect ophthalmoscopy is available.

Microscopy

Microscopy is the gold standard for establishing the diagnosis of malaria. Identification of typical parasite forms by an experienced microscopist is the mainstay of diagnosis worldwide (Figs. 220.3 through 220.7). There are many advantages of using light microscopy: it can be performed at low cost, it can be done rapidly, it typically allows identification of the infecting species and estimation of parasite load, and it can be

performed with a small sample of blood. The major disadvantage of microscopy is the need for an experienced microscopist. In settings where malaria is not endemic, the need for specialists to review microscope slides may lead to a delay in establishing the diagnosis.

Thin smears are the most useful in diagnosing malaria. They are easy to prepare, with only a single drop of blood required. The drop of blood is placed at one end of the slide, and the edge of a second slide is placed at the edge of the blood smear and drawn across the slide.¹¹⁹ RBC morphology is preserved by methanol fixation, so invasion of large RBCs by the parasites can be identified and speciation of the organism is possible (see Table 220.1). Oil-immersion magnification ($\times 1000$) should be used for viewing the slide because many young asexual intraerythrocytic parasites are only 2 to 3 μm in diameter and

may be missed when using high-dry ($\times 440$) magnification. The microscopist begins by looking at the thin edge of the blood film farthest from where the drop of blood was placed. Giemsa stain is preferred to Wright stain when available because it preserves details such as Schüffner dots in *P. vivax* and *P. ovale* infections. When individual RBCs can be seen at low magnification ($\times 100$), switching to oil immersion allows examination for parasites within the cells. The major disadvantage of thin films is low sensitivity. With low parasite loads (<100 to $300/\mu\text{L}$), the amount of blood on the smear may be too small to allow detection of the parasites.

Thick smears have greater sensitivity than thin smears as a result of the larger quantity of blood used. Because the RBCs are lysed during preparation of the slide, the types of cells containing parasites cannot

be identified. To make a thick smear, a drop of blood is placed on the slide and spread in a circle. The slide is stained without using methanol fixation so that RBCs lyse.

Estimating parasite density is useful for assessing degree of parasitemia and for evaluating response to therapy. The density of parasites can be determined on thick or thin smears.¹⁶⁸ When thin smears are used, the proportion of RBCs infected is counted while the smear is viewed under an oil-immersion lens.

Fluorescent Microscopy

The quantitative buffy-coat test relies on identification of parasitized RBCs stained with acridine orange in the RBC layer of centrifuged blood.¹⁶¹ Experienced personnel can perform the test rapidly, but the reagents are costly when compared with those needed for microscopy, and the species of parasite cannot be identified. If a fluorescent microscope is available, identification of parasitized RBCs can be accomplished by staining a thick smear with acridine orange and examining it under fluorescent light.

Detection of Parasite Antigen

Rapid diagnostic tests (RDTs) for diagnosis of malaria have been developed. These tests are immunochromatographic assays using monoclonal antibodies directed against target malaria antigens and require only 5 to 15 μ L of blood, with results obtained in 5 to 20 minutes.¹⁸⁰ Depending on the combinations of target antigens used, certain RDTs detect only *P. falciparum* antigens, whereas others can distinguish *P. falciparum* from *P. vivax*, *P. ovale*, and *P. malariae*. Assays detecting histidine-rich protein 2 (HRP-2) are specific for *P. falciparum*, whereas assays based on parasite LDH or HRP-2 and aldolase can identify four species of *Plasmodium*.^{37,91,105}

Compared with PCR, HRP-2 assays performed well, with sensitivity of 88% to 95% and specificity of 95% to 97%; when the HRP-2 assays were compared with microscopy, sensitivity ranged from 80% to 95% and specificity ranged from 85% to 100%.¹¹⁹ The tests also performed well when used in nonimmune travelers; a meta-analysis of 21 studies identified sensitivity of 88% to 98% and specificity of 95% to 100% for detection of *P. falciparum*.⁹⁸ The HRP-2/aldolase-based assays can detect four species of malaria, but they have a lower sensitivity for

diagnosis of vivax malaria, although this assay has a higher sensitivity for detection of malaria than the HRP-2 assays.^{26,67,105} A limitation of HRP-2-based assays is that they remain positive after therapy because HRP persists in the blood after acute infection. LDH-based assays are able to distinguish between *P. falciparum* and other malaria species, although the test is unreliable in detecting *P. vivax* in the presence of *P. falciparum*.¹³⁷ An advantage of LDH-based assays is the ability to distinguish between viable and nonviable parasites, rendering the test useful for monitoring response to therapy.^{23,28,67,105,125}

The target antigens, malaria species detected, sensitivity, and specificity of the four most commonly used RDTs in the United States are summarized in Table 220.3. The Binax Now test is the only RDT licensed in the United States.¹⁴ Although RDTs including Binax Now offer timely results without the use of microscopy, false-negative results are possible and can be problematic when there is low parasitemia. For this reason, many centers in the United States will perform diagnostic microscopy as a follow-up to a negative RDT; this approach reduces the risk of missing the diagnosis of malaria and should be performed when an experienced microscopist is available. Because RDTs do not allow for quantification of parasitemia, diagnostic microscopy should be pursued where available when a diagnosis of severe malaria is entertained, so that response to therapy can be monitored closely.

Dipstick tests may have a role in cost-effective diagnosis of malaria in situations in which laboratory services are inadequate, in mobile clinics or sites lacking electricity,¹⁸⁰ in locations where levels of malaria transmission are low and drug resistance is high, when the cost of treatment exceeds the cost of the dipstick test, and when blood smears are negative and determining the diagnosis is critical. In developed countries, dipstick assays can benefit laboratories with less experienced microscopists by helping them establish a rapid diagnosis, confirm a diagnosis made by microscopy, or determine the infecting species. Current limitations of the tests are decreased sensitivity compared with expert microscopy, especially at low levels of parasite density, cost, and lack of approval by the US Food and Drug Administration (FDA) of most of the tests.

Dipstick malaria tests have been proposed for use by travelers for self-diagnosis of malaria and have been tested for this purpose. The accuracy of both test performance and interpretation of results by

^aDirect microscopy should be performed where available with a negative RDT given higher false-negative rates with low parasitemia, and when severe malaria is suspected. HRP-2, Histidine-rich protein-2; RDT, rapid diagnostic test.

travelers has not been demonstrated as high enough to recommend this strategy routinely for travelers. Most experts suggest using the test to guide initial treatment while the traveler is heading to a source of health care for more definitive diagnosis and treatment.^{69,117}

DNA Probe

Specific DNA probes for identification of *P. falciparum* have been developed and tested in field conditions in Thailand.⁸ The technique compared favorably with microscopy and could be used to test large numbers of samples at a time, but it had the disadvantage of needing a radiolabeled probe. Nonisotope probes have been used in other field trials in Madagascar, where an enzyme-linked probe was compared with microscopy for diagnosis of falciparum malaria. Results were comparable to examination of thick smears by microscopy for *P. falciparum* infection, but the assay could not identify infection with *P. vivax*, *P. ovale*, or *P. malariae* alone.¹⁰¹

Polymerase Chain Reaction

PCR-based techniques used for establishing the diagnosis of malaria are highly sensitive and now are able to detect mixed infections. Compared with thick and thin smears, sensitivity and specificity are nearly 100%. PCR techniques can be useful for determining the species of an infection when microscopy is equivocal. Early detection of resistance to antimalarial drugs is another benefit of PCR-based techniques, which have been used to detect a mutation of *P. falciparum* associated with resistance to chloroquine.^{43,72} Currently, PCR is the only definite and validated means of diagnosing *P. knowlesi*, because this species may be confused with *P. malariae* on microscopy.⁸²

Major disadvantages of the PCR assay include the need for expensive equipment, reagents, and significant technical expertise and the length of time required to perform the testing. At this time, the PCR assay may be better suited for use in large-scale epidemiologic surveys, rather than for establishing the diagnosis of acute malaria in the clinical setting.

Flow Cytometry

Automated blood cell analyzers based on flow cytometry have been shown to display cells containing malaria pigment as a population of cells distinct from other blood components. To date, this discovery has been serendipitous in patients not suspected to have malaria and the diagnosis must be confirmed by conventional methods.^{55,73} A future application of this technology could be to modify automated blood cell analyzers to flag specimens that need to be examined further by thin or thick smears (or both).⁷³

Antibody Detection

Malaria antibodies develop rapidly after infection and remain present for years; they are of limited value in diagnosing malaria in individual patients. Occasionally, antibody tests might prove useful in the diagnosis of nonimmune individuals with cryptic febrile illnesses or on a population basis to assess the degree of community-wide immunity. Measurement of antibody may have a role in the diagnosis of hyperreactive malarial syndrome.¹⁸³

TREATMENT

Treatment of malaria depends on identification of the species of *Plasmodium* causing infection, knowledge of the presence of resistance to chloroquine and other drugs in the area in which malaria was contracted, and therapeutic goals (treatment of acute illness versus eradication of the exoerythrocytic phase of malaria). Drugs and classes of drugs currently in use for treating malaria include 4-aminoquinolines and related compounds (chloroquine, mefloquine [Lariam], amodiaquine); primaquine; sulfadoxine-pyrimethamine (Fansidar); halofantrine; atovaquone-proguanil (Malarone); artemisinin (qinghaosu) and other artemisinins (artemether, artesunate) and artemisinin drugs in combination with other agents; cinchona alkaloids (quinine, quinidine); and the antimicrobial agents doxycycline, tetracycline, and clindamycin. Investigational compounds and combination drugs are in various stages of development. Drugs that may be used for the treatment of malaria

in the United States are listed in Table 220.4. Drugs used for the prevention of malaria are discussed in a subsequent section.

The choice of agent to treat symptomatic malaria depends on the presence of resistance to chloroquine and other antimalarial drugs, the availability of drugs in the local area, and the age of the patient. Local and national guidelines for the treatment of malaria differ, and practitioners treating patients with malaria should consult local resources and experts. Country-specific information on the local areas with malaria, the estimated risk for malaria, whether there is chloroquine-resistant malaria, and which malaria species are present is available in the United States from the CDC (www.cdc.gov/malaria/travelers/country_table/a.html) and outside the United States from local and national health organizations and the WHO (www.who.int/malaria/diagnosisand_treatment.html).

In malaria-endemic areas, strategies such as intermittent treatment of infants and pregnant women are being employed in combination with use of insecticides and treated bed nets to prevent and treat malaria.¹⁵⁰ A full discussion of these programs is beyond the scope of this chapter.

Antimalarial Agents Available for Use in the United States

Chloroquine

Chloroquine is the drug of choice for chloroquine-susceptible malaria caused by *P. falciparum* and *P. vivax* and for all infections with *P. ovale* and *P. malariae*. Chloroquine is a 4-aminoquinoline with rapid schizonticidal activity. It is not effective against exoerythrocytic forms of the parasite, and patients treated with chloroquine after acquiring *P. vivax* or *P. ovale* infection need to have additional treatment to eliminate these forms. Chloroquine is most active against late ring stages and mature trophozoites. Response to treatment is rapid, with disappearance of parasitemia within 48 to 72 hours after initiation of treatment when the parasite is susceptible.

Chloroquine is available as an oral preparation and, outside the United States, as intramuscular and intravenous formulations. Oral absorption is excellent, and the drug is safe and effective when given by nasogastric or orogastric tube in comatose children.¹⁷⁷ Intramuscular and intravenous administration may be associated with an increased risk for cardiac arrhythmias, hypotension, and circulatory failure, and its use is discouraged by experts. There is a current prolonged shortage of chloroquine in the United States, and alternate medications for the treatment of malaria should be pursued without delay until this shortage is resolved.

Adverse reactions to chloroquine rarely occur at the doses used for prevention or treatment of malaria. Side effects include gastrointestinal symptoms such as nausea, vomiting, and diarrhea; dizziness; headache; and fatigue. Pruritus may be a troubling adverse event, especially in black patients. Chloroquine has no known teratogenic effects, and it may be used in pregnant and lactating women. The drug is not contraindicated in glucose-6-phosphate dehydrogenase (G6PD)-deficient individuals. Psychotic symptoms occur rarely with chloroquine.⁴⁸ Oral doses are absorbed rapidly. The lethal dose of chloroquine is 1 g in children and 4 g in adults. Cumulative doses exceeding 100 g are associated with an increased risk for development of retinopathy. Dose reduction is required for patients with severe renal impairment, and chloroquine should be used with caution in patients with hepatic impairment, alcoholism, or concurrent use of hepatotoxic drugs.

Artemether-Lumefantrine

Artemisinin (qinghaosu) is a sesquiterpene lactone that, along with its derivatives (artemether, artesunate, arteether, and others), has antimalarial activity thought to be due to the ability to cause free radical damage in parasite membrane systems.⁵⁹ These compounds are unique in their ability to cure malaria more rapidly than other agents, with rare adverse events. Significant hemolysis has been reported 13 to 15 days after treatment with artemisinin derivatives; this has occurred most frequently after treatment of patients with high parasite loads with parenteral artesunates.¹⁴² There is no consensus on the mechanisms through which artemisinin derivatives kill malaria parasites. Lumefantrine, a dichlorobenzylidene derivative, also has an unclear mechanism of action. The

Treatment course = 7 days.</p> <p>Investigational new drug (contact CDC for information): artesunate followed by one of the following: atovaquone-proguanil (Malarone), clindamycin, or mefloquine</p>

^aBased on drugs currently available for use in the United States. If outside the United States, contact national authorities about current recommendations. CDC, Centers for Disease Control and Prevention; G6PD, glucose-6-phosphate dehydrogenase; IV, intravenous; PO, by mouth.

^bIf a person develops malaria despite taking chemoprophylaxis, that particular medicine should not be used as part of their treatment regimen. Use one of the other options instead.

^cThree options (A, B, C, or D) are available for treatment of uncomplicated malaria caused by chloroquine-resistant *P. falciparum*. Options A, B, and C are equally recommended. Because of a higher rate of severe neuropsychiatric reactions seen at treatment doses, we do not recommend option D (mefloquine) unless the other options cannot be used. For option C, because there are more data on the efficacy of quinine in combination with doxycycline or tetracycline, these treatment combinations are generally preferred to quinine in combination with clindamycin.

^dTake with food or whole milk. If patient vomits within 30 minutes of taking a dose, they should repeat the dose.

^eUS manufactured quinine sulfate capsule is in a 324 mg dosage; therefore 2 capsules should be sufficient for adult dosing. Pediatric dosing may be difficult due to unavailability of noncapsule forms of quinine.

^fFor infections acquired in Southeast Asia, quinine treatment should continue for 7 days. For infections acquired elsewhere, quinine treatment should continue for 3 days.

^gDoxycycline and tetracycline are not indicated for use in children age <8 years. For children age <8 years with chloroquine-resistant *P. falciparum*, atovaquone-proguanil and artemether-lumefantrine are recommended treatment options; mefloquine can be considered if no other options are available. For children age <8 years with chloroquine-resistant *P. vivax*, mefloquine is the recommended treatment; if it is not available or is not being tolerated and if the treatment benefits outweigh the risks, atovaquone-proguanil or artemether-lumefantrine should be used.

^hTreatment with mefloquine is not recommended in persons who have acquired infections from Southeast Asia due to drug resistance.

ⁱWhen treating chloroquine-sensitive infections, chloroquine and hydroxychloroquine are recommended options. However, regimens used to treat chloroquine-resistant infections may also be used if available, more convenient, or preferred.

^jPrimaquine is used to eradicate any hypnozoite forms that may remain dormant in the liver and thus prevents relapses in *P. vivax* and *P. ovale* infections. Because primaquine can cause hemolytic anemia in G6PD-deficient persons, G6PD screening must occur prior to starting treatment with primaquine. For persons with borderline G6PD deficiency or as an alternate to the above regimen, primaquine may be given 45 mg orally one time per week for 8 weeks; consultation with an expert in infectious disease and/or tropical medicine is advised if this alternative regimen is considered in G6PD-deficient persons. Primaquine must not be used during pregnancy.

^kThree options (A, B, or C) are available for treatment of uncomplicated malaria caused by chloroquine-resistant *P. vivax*. High treatment failure rates due to chloroquine-resistant *P. vivax* have been well documented in Papua New Guinea and Indonesia. Rare case reports of chloroquine-resistant *P. vivax* malaria have also been documented in Myanmar (Burma), India, and Central and South America. Persons acquiring *P. vivax* infections outside Papua New Guinea or Indonesia should be started on chloroquine. If the patient does not respond, the treatment should be changed to a chloroquine-resistant *P. vivax* regimen and CDC should be notified. For treatment of chloroquine-resistant *P. vivax* infections, options A, B, and C are equally recommended.

^lFor pregnant women diagnosed with uncomplicated malaria caused by chloroquine-resistant *P. falciparum* or chloroquine-resistant *P. vivax*, treatment with doxycycline or tetracycline is generally not indicated. However, doxycycline or tetracycline may be used in combination with quinine (as recommended for nonpregnant adults) if other treatment options are not available or are not being tolerated, and if the benefit is judged to outweigh the risks.

^mAtovaquone-proguanil and artemether-lumefantrine are generally not recommended for use in pregnant women, particularly in the first trimester due to lack of sufficiency safety data. For pregnant women diagnosed with uncomplicated malaria caused by chloroquine-resistant *P. falciparum*, atovaquone-proguanil or artemether-lumefantrine may be used if other treatment options are not available or are not being tolerated and if the potential benefit is judged to outweigh the potential risks.

ⁿFor *P. vivax* and *P. ovale* infections, primaquine phosphate for radical treatment of hypnozoites should not be given during pregnancy. Pregnant patients with *P. vivax* and *P. ovale* infections should be maintained on chloroquine prophylaxis for the duration of their pregnancy. The chemoprophylactic dose of chloroquine phosphate is 300 mg base (= 500 mg salt) orally once per week. After delivery, pregnant patients who do not have G6PD deficiency should be treated with primaquine.

^oPersons with a positive blood smear or history of recent possible exposure and no other recognized pathology who have one or more of the following clinical criteria (impaired consciousness/coma, severe normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, disseminated intravascular coagulation, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, repeated generalized convulsions, and/or parasitemia of >5%) are considered to have manifestations of more severe disease. Severe malaria is most often caused by *P. falciparum*.

^pPatients diagnosed with severe malaria should be treated aggressively with parenteral antimalarial therapy. Treatment with IV quinine should be initiated as soon as possible after the diagnosis has been made. Patients with severe malaria should be given an intravenous loading dose of quinine unless they have received more than 40 mg/kg of quinine in the preceding 48 hours or if they have received mefloquine within the preceding 12 hours. Consultation with a cardiologist and a physician with experience in treating malaria is advised when treating malaria patients with quinine. During administration of quinine, blood pressure monitoring (for hypotension) and cardiac monitoring (for widening of the QRS complex and/or lengthening of the QTc interval) should be done continuously and blood glucose (for hypoglycemia) should be monitored periodically.

^qPregnant women diagnosed with severe malaria should be treated aggressively with parenteral antimalarial therapy. Modified from Centers for Disease Control and Prevention. Guidelines for Malaria Treatment in the United States. www.cdc.gov/malaria/resources/pdf/treatmenttable.pdf.

fixed dose combination of artemether (20 mg) and lumefantrine (120 mg) (Coartem) is available in the United States, is FDA approved, and is considered a first-line agent for treatment of uncomplicated falciparum malaria in countries where it is available. Artemether-lumefantrine is well tolerated and effective against multidrug-resistant falciparum malaria.¹⁴¹ A six-dose regimen compared favorably with other agents in African children and adults with uncomplicated falciparum malaria.^{108,130} Its side effect profile along with rapid parasite clearance and high cure rate for uncomplicated falciparum malaria in African infants and children make this regimen favorable.⁴² Bioavailability of lumefantrine is enhanced when it is taken with food.⁴¹

Artemether-lumefantrine is not approved for use in treatment of infection with *P. vivax*, *P. ovale*, or *P. malariae* because there are few data on its efficacy for infection with these species. There may be a role for the use of artemether-lumefantrine in treating chloroquine-resistant vivax malaria, because this drug combination produces rapid clearance of the blood stage. The short half-life of lumefantrine may, however, allow for a shorter time to relapse by dormant hypnozoites.^{9,182}

Atovaquone-Proguanil

A fixed-dose combination (available in adult and pediatric formulations) of atovaquone and proguanil hydrochloride is available for treatment of malaria caused by *P. falciparum* for individuals who were not taking this agent for prophylaxis. The combination is significantly more effective than either drug alone and is effective for treatment of malaria strains resistant to other antimalarial drugs. It has fewer reported adverse events than quinine-based regimens. The combination also is likely to be active against the blood stages of *P. vivax*, *P. ovale*, and *P. malariae*, but the regimen does not have activity against the hypnozoites of *P. vivax*. Atovaquone-proguanil is significantly more effective than mefloquine, chloroquine, amodiaquine, or pyrimethamine-sulfadoxine in locations where parasites are resistant to these drugs.⁸⁷

Mefloquine

The development of mefloquine was a major advance in the treatment of chloroquine-resistant malaria, although resistance has developed rapidly in some parts of the world where it is used widely. Mefloquine is a 4-quinolone-carbinolamine whose exact mechanism of action is unknown. Its main target is early trophozoites. Similar to chloroquine, it is not active against exoerythrocytic phases. Mefloquine has been associated with neurologic and psychiatric side effects when used for treatment or prophylaxis,¹⁶⁴ and in 2013 the US FDA updated their warnings regarding these potentially serious side effects. Vomiting occurs commonly when mefloquine is given to children younger than 5 years old and may decrease its efficacy.¹⁵⁹ Mefloquine should not be administered concurrently with quinine, quinidine, or halofantrine due to increased risk of developing arrhythmias. Pregnancy is not a contraindication to treatment in any trimester, although with the development of other well-tolerated medications, mefloquine is no longer the first choice for treatment of malaria in pregnancy.

Quinine and Quinidine

Quinine has been used for the treatment of malaria for centuries.¹⁶⁴ It is active against the mature asexual erythrocytic forms of all four species of human malaria and against the gametes of all species except *P. falciparum*, where it has activity only against immature gametes. It is not effective against exoerythrocytic forms. It may be given orally, intravenously, or intramuscularly. Quinine crosses the placenta easily and may be used in the treatment of pregnant women, although close monitoring for hypoglycemia is warranted.⁸⁸

Adverse reactions to quinine include tinnitus, headache, nausea, visual and hearing disturbances, and tremors, a constellation of symptoms called cinchonism. Symptoms may appear during the first 1 to 3 days of therapy and stop when treatment is terminated. Hypoglycemia may occur, particularly when the drug is used to treat pregnant women. Severe adverse events are rare but may occur idiosyncratically. Blackwater fever (hemoglobinuria) seems to occur after treatment with quinine, but the causal mechanism is unknown.

Recrudescence rates may be high when quinine is used alone because of the presence of quinine-resistant strains of *P. falciparum*, and a second

drug is needed to treat the remaining parasites. Drugs that may be used with quinine include doxycycline, tetracycline, and clindamycin.

Quinidine is a related drug that may be given intravenously; in countries where intravenous quinine is unavailable, it is a treatment option for severe malaria. The mechanisms of action and adverse events are similar, although cardiac arrhythmias occur more commonly with quinidine and cardiac monitoring is advised.¹⁷⁶

Primaquine

Primaquine, an 8-aminoquinoline derivative that is effective against exoerythrocytic hypnozoites, is used primarily to prevent relapses of infections with *P. vivax* and *P. ovale*, although it may not be completely effective against some strains of *P. vivax*. Despite adequate treatment with primaquine, relapses of infections with *P. vivax* and *P. ovale* do occur¹⁶; in some instances this may be due to inadequate dosing. It is not an effective blood schizonticide but is an active gametocidal and sporontocidal drug for the four main species of *Plasmodium* that cause human malaria. Primaquine can cause intravascular hemolysis in individuals with G6PD deficiency, and patients should be confirmed to have normal G6PD activity before using primaquine. Other adverse events include gastrointestinal symptoms such as nausea, epigastric pain, anorexia, and abdominal cramps. Rare side effects include methemoglobinemia, hemoglobinuria, and bone marrow suppression. Safety in pregnancy has not been established, and the drug should not be used by pregnant women. After delivery, women with *P. vivax* or *P. ovale* infections and without G6PD deficiency may be treated with primaquine.

Tetracycline and Doxycycline

Tetracycline, doxycycline, and the related drug minocycline have very slow activity against malarial schizonts.¹⁶⁴ Doxycycline and minocycline may be given once daily. They are active against chloroquine-resistant and pyrimethamine-sulfadoxine-resistant *P. falciparum*. Resistance to tetracycline has not been shown. Because of their slow activity, these agents should be given in combination with a rapidly acting drug such as quinine. These drugs should not be used in children younger than 8 years old or by pregnant or nursing women.

Antimalarial Agents Not Currently Available or Recommended for Treatment of Malaria in the United States

Other Artemisinin Derivatives

Aside from artemether-lumefantrine, the only artemisinin derivative available in the United States is parenteral artesunate, which is available on an emergency basis only from the CDC. Further study of late hemolysis especially after use of parenteral artesunate in high levels of parasitemia is needed.¹⁴² Other artemisinin derivatives are available in other parts of the world. When used alone, recrudescence rates are high, and the drug class has limited potential for prophylaxis. Oral preparations, suppositories, and oil-based preparations for intramuscular injection are available, although standardization of preparations is lacking.¹⁴¹ Combinations including artemisinins are the preferred antimalarial agents worldwide¹²¹ and have shown major utility in areas of multidrug-resistant *P. falciparum*.¹⁵⁹ In clinical trials in the Gambia, artemether was as effective as quinine and chloroquine for treatment of cerebral malaria in children.^{172,178} When used in sequence with mefloquine, the combination was effective and tolerated well by patients with acute, uncomplicated falciparum malaria in Thailand, an area with multidrug resistance.⁷⁶ Later studies showed that the use of this combination may have helped halt the progressions of mefloquine resistance in the region.¹¹⁶ Artemisinin-based combination treatments of falciparum malaria have been shown to be better tolerated and more effective than quinine and non-artemisinin combination therapies.²⁰ The use of artemisinin-based combination therapies has contributed to significant reductions in malaria burden in many parts of the world. There is, however, reduced susceptibility of *P. falciparum* to artemisinin derivatives in the Cambodia-Thailand border region, likely owing to use of the artemisinins as single-drug therapy as opposed to combination therapy, leading to a WHO-led program to contain artemisinin resistance in this region.³⁹ Emerging resistance to artemisinin derivatives in Southeast Asia has been documented; longer courses of artemisinin-based combination therapy may be required in these areas to achieve cure.⁷

Pyrimethamine-Sulfadoxine

The combination pyrimethamine-sulfadoxine, a sulfonamide plus a dihydrofolate reductase inhibitor, exhibits synergy in its action against malaria parasites; the combination is active even against strains resistant to the individual drug components. Although pyrimethamine-sulfadoxine has been used for presumptive treatment of malaria in travelers who are taking other drugs for prophylaxis in areas where chloroquine resistance occurs, widespread resistance to the drug combination and its slow action limits its use in nonimmune individuals with falciparum malaria. The CDC no longer recommends pyrimethamine-sulfadoxine for treatment of malaria. Although safety has not been established in pregnancy, the drug has been used widely and effectively for intermittent presumptive treatment of pregnant women in endemic areas to decrease the risk for severe anemia and placental malaria.^{36,156,158}

Amodiaquine

Amodiaquine, similar to chloroquine, is a 4-aminoquinolone. It has similar efficacy but may have increased activity compared with chloroquine for the treatment of strains of *P. falciparum* resistant to chloroquine.¹²⁰ It is available in an oral preparation and is more palatable than chloroquine. Significant adverse events, including agranulocytosis, hepatotoxicity, and death, when used as a prophylactic agent have limited its use as a first-line agent. It is not licensed or marketed in the United States, though its use is increasing outside the United States.

Halofantrine

Halofantrine is a 9-phenanthrene-methanol that has been used to treat malaria caused by chloroquine-resistant *P. falciparum*. Its major side effect is dose-related prolongation of the QT interval, and it has been associated with cardiac arrhythmias and sudden death, especially in individuals taking mefloquine prophylaxis.^{115,163} Its major use was in uncomplicated malaria in areas of multidrug resistance, but cardiac toxicity at the doses required to be effective and mounting resistance limit its widespread use.¹⁶⁶ It is contraindicated in pregnant and lactating women because of embryotoxic effects. Travelers who are taking mefloquine for prophylaxis should be cautioned against accepting treatment with halofantrine if they are diagnosed with malaria during their travels. Halofantrine is unavailable in the United States.

Supportive Therapy

Malaria is a potentially fatal illness even in patients who may have developed partial immunity. Children and those without prior immunity with falciparum malaria should have immediate treatment and generally should be admitted to the hospital, especially in nonendemic countries such as the United States. Patients with severe malaria should be managed in intensive care units, and experts in treatment of malaria and its complications should be consulted. Blood smears should be examined at least every 12 to 24 hours (and every 4 to 6 hours for severe malaria) until parasitemia is less than 1%. Patients with uncomplicated malaria can be treated with oral medication, although patients should be switched promptly to parenteral medication if oral medication is not tolerated. CDC (www.cdc.gov/malaria/pdf/treatmenttable.pdf) and WHO (www.who.int/malaria/diagnosisandtreatment.html) guidelines for treatment of malaria, including management of severe malaria, are available.

Goals of supportive therapy are to maintain oxygenation and treat acidosis and hypoglycemia. Treatment with dextrose infusion, oxygen, and blood transfusion may be necessary. Mechanical ventilation with positive-pressure ventilation may be needed to manage acidosis and acute respiratory distress syndrome. In some cases, hemodialysis may be needed. A high index of suspicion should be maintained for other concomitant or nosocomial infections, such as meningitis or septicemia.

Investigational Drugs and Adjunctive Therapy

Targets for new antimalarial drugs include malaria proteases and protein kinases, which play a crucial role in malaria pathogenesis.^{38,147} These drugs are largely in the development phase.

A novel primaquine analogue, tafenoquine, is currently under investigation for use in prophylaxis and treatment of *P. falciparum* and *P. vivax* malaria in African countries. The advantages of this drug are

its long half-life, activity against liver-stage malaria parasites, and favorable therapeutic and safety profile.^{83,110,154} As with primaquine, G6PD activity must be measured prior to its use.

Adjunctive therapies that have been shown to be beneficial include antipyretic and anticonvulsant drugs. Exchange transfusion remains a controversial option^{168,176} largely owing to the lack of sufficient randomized controlled trials. Exchange transfusion may decrease parasite clearance times compared with quinine alone,¹⁷¹ but there is a lack of clear survival benefit with exchange transfusion.¹⁴³ Adjunctive therapies that would modify or prevent the deleterious effects of inflammatory mediators, oxidative stress, iron overload, acidosis, and hypercoagulability in severe and cerebral malaria have been proposed, but limited clinical studies have not shown significant benefit.⁷¹ A randomized study of inhaled nitric oxide in severe malaria is ongoing.⁵⁶ Some therapies, such as high-dose corticosteroids for cerebral malaria or heparin, have been shown to be harmful.^{176,181} The search for effective adjunctive therapy for severe and complicated malaria continues.

PREVENTION

Prevention of malaria can be accomplished by reducing the mosquito population, using personal protection methods to prevent mosquito bites, and using chemoprophylaxis. Reduction of mosquito vectors is most successful when locally controlled programs are developed and maintained.⁷⁸ Strategies that combine personal protective measures with community-based control measures, such as distribution of insecticide-treated mosquito nets and indoor residual spraying, are most likely to be successful.¹²² Most programs in endemic areas require a combination of preventive strategies and effective treatment modalities. Many nonendemic countries have developed recommendations for prevention of malaria in travelers.

Personal Protective Measures

A significant reduction in the incidence of malaria in children in communities where bed nets, especially when impregnated with insecticide, are used consistently has been reported from many countries.^{34,49,160} In northern Ghana, community-wide use of bed nets was associated with a reduction in all-cause child mortality in young children.¹⁴ Use of bed nets, especially those impregnated with insecticide, is recommended for travelers to malarial areas. Other personal protective measures include using mosquito repellents and insecticide-impregnated clothing or gear; wearing clothing that covers areas likely to be bitten; and residing in air-conditioned or well-screened areas during times when mosquitoes are biting. Diethyltoluamide (DEET)-containing repellents are recommended most commonly for prevention of mosquito bites and are highly effective.⁴⁵ Other agents, such as picaridin, oil of lemon eucalyptus, and IR3535, are available. Picaridin is available in a 20% formulation, which may be used as an alternative to DEET.¹²⁹ Other agents have not been studied extensively against *Anopheles* mosquitoes.

Chemoprophylaxis

Country-specific information regarding recommendations for the use of antimalarial drugs may differ, and readers are urged to seek recommendations from national or local authorities. In the United States, these recommendations are available widely in publications from the CDC¹³⁴ or national health information sources. Many excellent sources of health information for travelers include discussions of malaria prevention.^{21,22,24,95,149,155,162} The Infectious Diseases Society of America has published detailed pre-travel guidelines that include recommendations for malaria prevention.⁶⁰ A list of drugs available for malaria prevention is presented in Table 220.5. Prevention of malaria for travelers is best discussed in the context of providing complete pre-travel services, advice, and information.

Antimalarial Agents Available in the United States for Prevention of Malaria

Chloroquine and Hydroxychloroquine

A major determinant of appropriate chemoprophylaxis is whether a patient is to travel to an area of chloroquine resistance. In areas of the

TABLE 220.5 Drug Regimens Used for Prevention of Malaria

Drug	Adult Dosage	Pediatric Dosage	Comments
Chloroquine-Sensitive Areas			
Chloroquine phosphate (drug of choice)	500 mg salt (300 mg base) orally once/wk	8.3 mg/kg salt (5 mg/kg base) once/wk, up to adult dose of 300 mg base	Begin 1–2 wk before exposure, continue during exposure, and continue for 4 wk after exposure May be used in pregnant women
Hydroxychloroquine sulfate	400 mg salt (310 mg base) orally once/wk	6.5 mg/kg salt (5 mg/kg base) orally once/wk	Begin 1–2 wk before exposure, continue during exposure, and continue for 4 wk after exposure An alternative to chloroquine for use only in areas with chloroquine-sensitive malaria
Chloroquine-Resistant Areas			
Atovaquone-proguanil	250 mg/100 mg (1 tablet) daily	5–8 kg: ½ pediatric tablet daily 9–10 kg: ¾ pediatric tablet daily 11–20 kg: 1 pediatric tablet daily 21–30 kg: 2 pediatric tablets daily 31–40 kg: 3 pediatric tablets daily >40 kg: 1 adult tablet daily	Begin 1–2 days before exposure, continue during exposure, and continue for 7 days after exposure Pediatric tablets contain 62.5 mg atovaquone and 25 mg proguanil hydrochloride See text for contraindications
Mefloquine	250 mg salt (228 mg base) orally once/wk	≤9 kg: 5 mg/kg salt (4.6 mg/kg base) orally once/wk 10–19 kg: ¼ tablet orally once/wk 20–30 kg: ½ tablet orally once/wk 31–45 kg: ¾ tablet orally once/wk >45 kg: 1 tablet orally once/wk	Begin 1–2 wk before exposure, continue during exposure, and continue for 4 wk after exposure See text for contraindications
<i>Or</i>			
Doxycycline	100 mg daily	2.2 mg/kg/day up to 100 mg/day	Begin 1–2 days before exposure, continue during exposure, and for 4 wk after exposure; not to be used in children >8 yr or pregnant women
<i>Or</i>			
Alternative			
Primaquine	52.6 mg salt (30 mg base) orally daily	0.8 mg/kg salt (0.5 mg/kg base) up to adult dose orally daily	Begin 1–2 days before exposure, continue during exposure, and continue for 7 days after exposure Contraindicated in people with G6PD deficiency, in pregnancy, and during lactation Prophylaxis to areas principally with <i>P. vivax</i>

world that have no resistance to chloroquine, the drug of choice for prevention of malaria is chloroquine or hydroxychloroquine. This drug class is tolerated well and may be given to children and adults of all ages, including infants. Dosing of chloroquine and hydroxychloroquine in children is based on the child's weight and can be found in Table 220.4. In the United States, chloroquine is available only in tablets that have a very bitter taste. Pharmacies can also prepare appropriate doses in capsules, and the contents of the capsule can be mixed with a small amount of liquid or semisolid food for administration. Although liquid preparations are widely available overseas and are stable for long periods,¹⁰⁴ many US pharmacies are reluctant to prepare them. If patients are considering purchasing liquid preparations overseas, the family should be given information with the child's medication dose calculated as the base and the salt because concentrations of liquid preparations may vary. Families also should be cautioned about the greater incidence of ineffective or counterfeit medications available in some areas. In 2015, the US FDA issued a drug shortage alert for chloroquine, and this has yet to be resolved, limiting its current use. Hydroxychloroquine was recently on shortage, but the shortage has since been resolved.

Adverse events caused by chloroquine are uncommon when the medication is used at doses needed for malaria prophylaxis. Minor side effects include gastrointestinal upset, headache, dizziness, blurred vision, and pruritus. Adverse events rarely require discontinuation of medication. Chloroquine may be taken during pregnancy and is not contraindicated in children with G6PD deficiency.

The choice of antimalarial agents in locations where drug-resistant parasites have been identified is more challenging. Chloroquine-containing regimens are not recommended for travel to areas with known chloroquine-resistant *P. falciparum*, and deaths from malaria

have occurred when these regimens have been used.⁹³ The choice of regimen depends on the type of drug resistance, length of stay, age of the traveler, and individual medical history. Drugs currently available in the United States include mefloquine, doxycycline, atovaquone-proguanil, and primaquine.

Atovaquone-Proguanil

Atovaquone-proguanil is the most common choices for malaria chemoprophylaxis because of the favorable side effect profile and the need to take the medication once daily for only 1 to 2 days before and 7 days after leaving the area of risk for malaria. Once-weekly dosing of atovaquone-proguanil for prophylaxis may be possible, but larger field trials are needed before this can be recommended.³⁵ The drug is effective against most *P. falciparum*, including resistant strains. It is available in adult and pediatric dosing formulations and is administered daily. Adverse events most commonly reported with atovaquone-proguanil are abdominal pain, nausea, vomiting, and headache. Some of these adverse events can be mitigated by taking the drug with food; absorption is also better when taken with a fatty meal. It is not recommended at this time for prophylaxis of infants weighing less than 5 kg, for mothers nursing such infants, or for pregnant women.

Mefloquine

Mefloquine generally is well tolerated in children and can be given to infants. Dosing is based on weight, and no liquid preparation is available. Doses for older children can be supplied by breaking tablets; when small fractions of tablets are needed, pharmacists can provide individual doses in capsules. The medication has a pasty consistency but does not taste as bitter as chloroquine. Infants tend to swallow doses better when

given liquids or semisolid foods after the medication. Adverse events with mefloquine are self-limited in most cases and include gastrointestinal disturbance, insomnia, and dizziness.⁸⁵ Withdrawal rates in adults, presumably caused by the incidence of these adverse events, may impair the efficacy of mefloquine.³¹ Rarely, serious adverse events, such as psychosis or seizures, have occurred after prophylactic doses of mefloquine, prompting an updated warning from the US FDA in 2013. This black box warning requires that providers review an information sheet and read the details of the warning prior to prescribing mefloquine and has decreased the use of mefloquine for malaria prophylaxis. Mefloquine should not be used in individuals who have seizures or neuropsychiatric disorders or in individuals who have had previous adverse events with mefloquine. Mefloquine also is contraindicated in patients with cardiac conduction abnormalities, although it may be used in individuals concurrently taking β -blockers for indications other than arrhythmias.

Mefloquine must be taken weekly, beginning 1 to 2 weeks before travel (with some experts recommending initiation up to 4 weeks before travel) and continued for 4 weeks after leaving the malarial area. Families may be counseled to choose a day of the week to take the medicine and to take their first dose or doses on that day of the week 1 to 2 weeks before departure. Mefloquine may be used by pregnant women in any trimester of pregnancy.^{114,173}

Doxycycline

Doxycycline is an effective antimalarial drug in parts of the world where chloroquine resistance is present. It also has been shown to be effective in areas where mefloquine-resistant *P. falciparum* exists, such as portions of Cambodia, Myanmar (Burma), Vietnam, and Thailand. Limitations in the use of this drug include that it is contraindicated in children younger than 8 years, need for daily dosing, and photosensitivity. In women, daily use of doxycycline may be associated with an increased risk for *Candida* vulvovaginitis. Gastrointestinal side effects, including nausea and vomiting, can be limited by taking the medication with meals and by avoiding bedtime dosing. Doxycycline must not be used by pregnant or lactating women. Prophylaxis with doxycycline needs to begin 1 to 2 days before travel and should be continued daily for 4 weeks after leaving the malarial area.

Primaquine

Primaquine is used most often to eradicate exoerythrocytic stages of *P. vivax* and *P. ovale*. The CDC recommends primaquine for chemoprophylaxis primarily in regions with predominantly vivax malaria. Individuals must be tested and shown not to be deficient in G6PD before they take this drug. Efficacy of primaquine compared favorably with that of mefloquine, doxycycline, and chloroquine plus proguanil in children in the holoendemic area of western Kenya.^{47,151,175} It cannot be used in pregnant women.

Antimalarial Agents Not Available or Recommended in the United States for Prevention of Malaria

Tafenoquine

Tafenoquine is an investigational long-acting primaquine analogue that kills parasites in the liver and in blood. It is thought to be more effective and less toxic than primaquine, but it cannot be used by individuals with G6PD deficiency or by pregnant women. No dosing regimen has been established, and it is not licensed for use,^{54,153,174} but it may be available in the future.^{62,74,153}

Proguanil

Proguanil has been used in combination with chloroquine to prevent chloroquine-resistant *P. falciparum*, but it is less effective than mefloquine and is not recommended or available as a single agent in the United States.

Pyrimethamine-Sulfadoxine

Pyrimethamine-sulfadoxine has been used for prevention of malaria in areas of chloroquine-resistant *P. falciparum*. An unacceptably high incidence of Stevens-Johnson reactions (fatalities in one in 11,000 to

25,000 users) resulted in withdrawal of the indication for using this drug for malaria prophylaxis.

Standby Emergency Self-Treatment

Standby emergency treatment (SBET) is the self-administration of antimalarial drugs when malaria is expected and prompt medical attention is unavailable within 24 hours of the onset of symptoms. The goal of SBET is to prevent death or severe malaria. This strategy is intended for emergency use only and is considered when the risks of toxicity from chemoprophylactic drugs outweigh the benefit of avoided infection. SBET should not be recommended for travelers to high-risk *P. falciparum*-endemic areas, where chemoprophylaxis is the preferred strategy. SBET is an option for clearly defined situations, and its use must be weighed carefully with the traveler's ability to use SBET as directed.^{124,135}

Intermittent Preventive Treatment

Intermittent preventive treatment in infants (IPTi) and children (IPTc) is a strategy entertained in sub-Saharan Africa to reduce malaria disease burden especially in children who are at higher risk of fatal disease. The impact of IPTi and IPTc on the development of immunity, transmission of malaria parasites and the development of antimalarial resistance are yet to be defined in the field³ but are areas of current study.

Vaccine

Vaccination against malaria has been a subject of active research for several decades, but a licensed vaccine is not yet available. Development of a vaccine is challenging because of the complexity of the parasite life cycle, heterogeneity of the host immune response, lack of animal models, and absence of surrogate markers of protection. Testing of vaccines is difficult because vaccine efficacy depends on conditions of transmission and the degree of immunity present in the population being studied.¹⁶⁷ Targets for development of a vaccine include the sporozoite (prevention of infection), the merozoite (prevention of disease manifestations by preventing invasion of RBCs), and the gametocyte (prevention of transmission by interfering with development of the parasite within the mosquito). Hundreds of candidate vaccine antigens have been identified by the *P. falciparum* genome project; choosing the most promising ones is challenging.⁵³

The first malaria vaccines were directed against circumsporozoite antigen, an antigen present over most of the surface of the sporozoite. Development of these vaccines was based on the concept that sporozoites should be susceptible to antibody-mediated destruction in the extracellular space. Results of early studies with these vaccines were disappointing, with inadequate protection provided against sporozoite challenge, inconsistent relationships between antibody response and clinical efficacy, and numerous local side effects.^{58,61} More recently, the candidate vaccines RTS,S/AS02A and RTS,S/AS01E have shown promise in trials in Mozambique⁵ and Kenya.¹³ The candidate vaccine RTS,S/AS01, currently being studied in a phase III trial in seven African countries, has shown vaccine efficacy of 50.4% against malaria, with efficacy against severe malaria of 45.1%.² Recent phase II data in African children have shown that anti-circumsporozoite protein IgG avidity is similar after second and third doses of RTS,S/AS01 vaccines, and further study relating the IgG avidity to vaccine efficacy is needed.⁴ Merozoite surface proteins are another group of antigens that have been studied in connection with the development of a blood-stage, or asexual, malaria vaccine.¹²⁶ The SPf66 vaccine, derived from three merozoite proteins linked to a 4-amino acid from a *P. falciparum* circumsporozoite protein, has been tested in clinical trials in Colombia, Tanzania, and the Gambia.^{6,34,170} Although initial studies in countries in South America with low malaria endemicity showed promise, investigations in African countries with high endemicity have been disappointing, with protective efficacy ranging from 31% (95% confidence interval [CI], 0–52%) in Tanzania to 8% (95% CI, 18–29%) for first or only clinical episodes and 3% (95% CI, –24% to 24%) in overall incidence of clinical episodes in the Gambia.

Vaccines that block transmission from humans to mosquitoes would reduce the reservoir of infected mosquitoes and reduce transmission on a population level. The poor immunogenicity and diversity of gametocyte antigens have proved challenging to this approach to the

development of a vaccine, and no vaccines of this type have been used yet in clinical trials. Future vaccines are likely to use a combination approach that incorporates target antigens from all three stages of the parasite. To have a significant impact on decreasing worldwide burden of malaria, vaccines ultimately may need to be combined with other prevention strategies, including protection against mosquito bites with insecticides and treated bed nets and intermittent preventive treatment with antimalarial drugs.⁵³

Leishmaniasis

Lynne S. Garcia

Leishmaniasis is a parasitic disease affecting more than 12 million people in over 95 countries, with 350 million more at risk and 2 to 2.5 million new cases reported each year.^{22,36,53} The infection consists of a group of diseases that may affect the skin, mucous membranes, and/or viscera, with a wide range of clinical presentations caused by obligate intracellular hemoflagellates of the genus *Leishmania*. Infection is transmitted by several genera and species of phlebotomine sandflies. Four major clinical syndromes usually are recognized: cutaneous (CL), mucocutaneous (MCL), visceral (VL), and American tegumentary (cutaneous) (ATL) leishmaniasis. Macrophages of the skin, mucous membranes, and/or spleen, liver, and bone marrow (reticuloendothelial system) are parasitized. New species continue to be identified, particularly in the New World. However, the taxonomy of leishmaniasis is controversial, and species differentiation is currently based on molecular techniques rather than morphology and clinical presentation.¹²

Studies on the components of sandfly saliva suggest that substances may partially influence the tropism of the parasite and therefore the resulting disease. The amount of a vasodilatory peptide, maxadilan, in sandfly saliva appears to correlate with the type of human infection.⁶⁰ Sandflies in Brazil that transmit *Leishmania chagasi* VL have relatively large amounts of maxadilan, in their saliva, which causes marked vasodilation and may encourage visceralization of the parasites. The same complex of sandflies in Costa Rica, which have relatively small amounts of the vasodilatory peptide in their saliva, transmit organisms that produce a nonulcerating and nonvisceralizing *L. chagasi* infection that is limited to the dermis.

The clinical manifestations of leishmaniasis appear to depend on a complex set of factors, including tropism and virulence of the parasite

strain, as well as the susceptibility of the host, which may be determined genetically.¹⁰ Cell-mediated immune mechanisms appear to be the major factors in modulating these diseases (Table 221.1). However, specific pathway factors responsible for the generation of virulent amastigotes in human infections are still poorly understood.^{10,50} Disease syndromes range from self-healing cutaneous lesions to debilitating mucocutaneous infections, subclinical viscerotropic dissemination, and fatal visceral involvement.

In CL, *Leishmania tropica* (with some notable exceptions), *Leishmania major*, *Leishmania aethiopica*, and *Leishmania mexicana* tend to be restricted to reticuloendothelial cells of the skin, and infections generally are self-limited, with spontaneous healing. Similarly, in MCL *Leishmania braziliensis* can invade the reticuloendothelial cells of the skin and the mucous membranes of the nose, mouth, and pharynx, resulting in serious disfigurement, if not death. Some strains of *L. tropica* may cause viscerotropic disease. In cases of VL (kala-azar), *Leishmania donovani*, *Leishmania chagasi*, and *Leishmania infantum* invade cells of the reticuloendothelium of viscera, usually causing splenomegaly and occasionally hepatomegaly and pancytopenia; untreated, the disease is progressive and generally fatal.⁴⁶

In ATL, *Leishmania* (*Viannia*) *braziliensis* and *L. (Leishmania) mexicana* have an annual incidence of 1 to 1.5 million cases. Some patients, when self-cure of the cutaneous lesions does not occur, will develop the disseminated form of the disease.^{71–73}

Individuals with acquired immunodeficiency syndrome (AIDS) may have atypical manifestations. Dermotropic strains of *L. infantum* are known to cause visceral infection in immunocompromised patients with AIDS.⁵⁷ VL is quite prevalent among AIDS patients in certain

Leishmaniasis

TABLE 221.1 Clinical Syndromes Caused by *Leishmania* Species and Their Geographic Distribution^a

Clinical Syndromes	<i>Leishmania</i> Species ^b	Location
Visceral Leishmaniasis		
Kala-azar: Generalized involvement of the reticuloendothelial system (i.e., spleen, bone marrow, liver)	<i>L. (L.) donovani</i>	Indian subcontinent, northern and eastern China, Pakistan, Nepal
	<i>L. (L.) infantum</i>	Middle East, Mediterranean littoral, Balkans, Central and southwestern Asia, northern and northwestern China, northern and sub-Saharan Africa
	Canine visceral leishmaniasis	Foxhounds in 18 states (United States)
	<i>L. (L.) donovani (archibaldi)</i>	Sudan, Kenya, Ethiopia
	<i>L. (L.) spp.</i> ^a	Kenya, Ethiopia, Somalia
	<i>L. (L.) chagasi</i>	Latin America
	<i>L. (L.) amazonensis</i>	Brazil (Bahia State)
Post-kala-azar dermal leishmaniasis	<i>L. (L.) tropica</i>	Israel, India, and viscerotropic disease in Saudi Arabia (US troops)
	<i>L. (L.) donovani</i>	Indian subcontinent, East Africa
Old World Cutaneous Leishmaniasis		
Single or limited number of skin lesions	<i>L. (L.) major</i>	Middle East, northwestern China, northwestern India, Pakistan, Africa
	<i>L. (L.) tropica</i>	Mediterranean littoral, Middle East, western Asiatic area, Indian subcontinent
	<i>L. (L.) aethiopica</i>	Ethiopian highlands, Kenya, Yemen
	<i>L. (L.) infantum</i>	Mediterranean basin
	<i>L. (L.) donovani (archibaldi)</i>	Sudan and East Africa
	<i>L. (L.) spp.</i>	Kenya, Ethiopia, Somalia
Diffuse cutaneous leishmaniasis	<i>L. (L.) aethiopica</i>	Ethiopian highlands, Kenya, Yemen
New World Cutaneous Leishmaniasis (Includes American Tegumentary Leishmaniasis^c)		
Single or limited number of skin lesions	<i>L. (L.) mexicana</i> (chiclero ulcer)	Central America, Mexico, Texas, Oklahoma, Arizona
	<i>L. (L.) amazonensis</i>	Amazon basin and neighboring areas, Bahia and other states in Brazil
	<i>L. (V.) braziliensis</i>	Multiple areas of Central and South America
	<i>L. (V.) guyanensis</i> (forest yaws)	Guyana, Suriname, northern Amazon basin
	<i>L. (V.) peruviana</i> (uta)	Peru (western Andes) and Argentinean highlands
	<i>L. (V.) panamensis</i>	Panama, Costa Rica, Colombia
	<i>L. (V.) pifanoi</i>	Venezuela
	<i>L. (V.) venezuelensis</i>	Venezuela
	<i>L. (V.) colombiensis</i>	Colombia and Panama
	<i>L. (L.) chagasi</i>	Central and South America
Diffuse cutaneous leishmaniasis	<i>L. (L.) amazonensis</i>	Amazon basin and neighboring areas, Bahia and other states in Brazil
	<i>L. (V.) pifanoi</i>	Venezuela
	<i>L. (L.) mexicana</i>	Mexico and Central America
	<i>L. (L.) spp.</i>	Dominican Republic
Mucosal leishmaniasis	<i>L. (V.) braziliensis</i> (espundia)	Multiple areas in Latin America

^aThis table contains the most common species; not every organism is listed above.

^b>(*L.*) subgenus *Leishmania*; (*V.*) subgenus *Viannia*.

^cThese two organisms are the primary cause of American tegumentary leishmaniasis from the southern United States to the southern part of Argentina.

Data from Laison R, Shaw JJ. Evolution, classification and geographic distribution. In: Peters W, Killick-Kendrick R, eds. *The Leishmaniases in Biology and Medicine*. London: Academic Press; 1987:1–120; modified from Pearson RD, Sousa AQ. Clinical spectrum of leishmaniasis. *Clin Infect Dis* 1996;22:1–13; from Pearson RD, Jeronimo SMB, de Queiroz A. Leishmaniasis. Leishmaniasis worldwide and global estimates of its incidence. *PLoS One*. 2012;7:e35671.

geographic areas (southern Spain), with a high proportion of cases being subclinical. Like other opportunistic infections, subclinical VL can be found at any stage of HIV-1 infection, but symptomatic cases appear mainly when severe immunosuppression is present.⁵² HIV-*Leishmania* coinfection is being seen more and more frequently in the Mediterranean basin, especially in Spain, France, and Italy.

ORGANISM

In vertebrate hosts, *Leishmania* spp. are obligate intracellular parasites that exist only in the amastigote stage. The species that infect humans are usually morphologically indistinguishable from one another at both the light microscopic and ultrastructural levels. The organisms are round to oval bodies approximately 2 to 4 μ m in diameter with a single nucleus, a specialized mitochondrial structure that has extranuclear DNA termed a *kinetoplast*, and no free flagellum. Amastigotes are engulfed by macrophages and reside within the parasitophorous vacuole of the macrophage host. They multiply by binary fission and eventually destroy the host cell. Subsequently, they are phagocytized, and the process occurs repeatedly.²⁷

When the vector, a female sandfly, feeds on an infected person, it may ingest an infected cell from blood or tissue. Amastigotes are liberated in

the fly's midgut, and within a few hours, transformation to the promastigote stage occurs. Promastigotes are elongated flagellates 15 to 25 μ m long by 1.5 to 3.5 μ m wide, each with an anterior, free flagellum that measures approximately 15 to 28 μ m in length and may vary morphologically from a short and stumpy to an elongated form. Binary fission then begins, and large numbers of promastigotes are produced and gradually move forward to the pharynx, buccal cavity, and mouth parts. Depending on temperature and the species of sandfly, at 8 to 20 days, the mouth parts of the fly may be blocked partially or completely by huge numbers of promastigotes. These organisms may be dislodged into the bite wound when the female sandfly (*Phlebotomus*, *Lutzomyia*) next takes a blood meal. Promastigotes have surface molecules that bind to several macrophage receptors. The phagocytized promastigote forms transform into amastigotes within the parasitophorous vacuole, and multiplication takes place.

Amastigotes can be seen in Giemsa- or Wright-stained tissues or smears by light microscopy with the nucleus and kinetoplast staining bright red and the cytoplasm pale blue. Other blood stains are also acceptable. In Novy-MacNeal-Nicolle (NNN) culture medium at 24°C, the organisms grow readily and assume the promastigote or insect form.

In the past, specific and subspecific taxonomy designations have been determined by the clinical syndrome caused by an isolate in a

particular geographic area. Also, various molecular techniques have been used to characterize the strains and species of clinical isolates: endonuclease restriction studies of kinetoplast DNA (K-DNA), buoyant density of K-DNA and mitochondrial DNA (M-DNA) on cesium chloride, leishmanial isozyme patterns, monoclonal antibody specificity, exoantigen secretory factor 4 serotyping, polymerase chain reaction (PCR) real-time PCR, nucleic acid sequence-based amplification (NASBA), and loop-mediated isothermal amplification (LAMP).^{5,21}

EPIDEMIOLOGY

Leishmaniasis is mainly a zoonosis, although in certain areas of the world there is primarily human-vector-human transmission. The World Health Organization (WHO) estimates that 1.5 million cases of CL and 500,000 cases of VL occur every year, with 62,500 yearly deaths.^{2,30} From 2005 to 2013, the number of Disability Adjusted Life Years (DALYs) for leishmaniasis increased to 4.283 million.²⁹ With recent outbreaks in many areas of the world, including Brazil, India, Italy, Spain, Sudan, and Kenya, leishmaniasis has become more widely recognized as an important emerging infectious disease in many developed as well as underdeveloped countries.^{58,61} As of 2013, there were 3.914 million prevalent cases of CL and 113,700 prevalent cases of VL.²⁸ Although the parasite usually is transmitted via the bite of the sandfly vector, it may be transmitted also as a result of a laboratory accident, direct person-to-person transmission, and blood transfusion.^{27,45} In addition, evidence indicates that it may be transmitted either in utero or during the peripartum period.

The phlebotomine sandfly, the vector for leishmaniasis, was first identified in 1691 by Bonanni.²³ The name of the genus, however, *Phlebotomus*, was coined in 1840 by Rondani and Berte. In 1907, the first description of an American phlebotomine sandfly was made by Coquillett. In 1909 Gaspar Vianna in Brazil identified the parasites responsible for cutaneous leishmaniasis, later identified as *Leishmania braziliensis* in 1911.¹⁹ Concurrently Lutz and Neiva identified the first three species of sandflies in Brazil. *Lutzomyia* sandflies were later named after Adolfo Lutz. To date 229 species have been identified. It was not until 1921, however, that the Sergent brothers implicated the phlebotomine sandflies in the transmission of cutaneous leishmaniasis in Algeria. The evidence was substantiated by the work of Aragao in 1922 and Pessoa and Pestana in Brazil, in 1940. Later in 1950, it was discovered that the different forms of leishmaniasis infesting the American continent were caused by distinct species of the parasite. The research on leishmaniasis and sandflies has shed light on the transmission of other zoonotic illnesses, including trypanosomatids (*Crithidia*, *Endotrypanum*, *Trypanosoma*), and several viruses including Rhabdoviridae, Bunyaviridae, and Reoviridae, all isolated from phlebotomine sandflies. Sixty-nine different serotypes of arboviruses isolated from sandflies have been identified in the Amazon region.²³

OLD WORLD CUTANEOUS LEISHMANIASIS

Definition and Epidemiology

Old World CL is caused by *L. major* (rural), *L. tropica* (urban), and *L. aethiopica*. It is found throughout the Middle East, along the Mediterranean basin and islands, and in East and West Africa, India, and southwestern Asia.²⁷ There has been a large increase in *L. tropica* cases in Afghanistan and Syria due to the military conflicts in occupied territories.⁴⁰ In humans, infection by *L. tropica* usually produces skin ulcers in which intracellular (amastigote) parasites can be found within macrophages in and around the lesions. These organisms are rarely found in spleen, liver, or bone marrow; however, several recent reports have described *L. tropica* isolates from patients with VL. In many areas, dogs or rodents are found to be naturally infected and are thought to be the natural reservoirs of infection. Various *Phlebotomus* spp. transmit the infection, although person-to-person transmission is possible and is the basis of the long-time practice in middle and central Asia of immunizing inoculation, that is, "leishmanization" to prevent possible disfigurement by a natural infection (Fig. 221.1).

Old World leishmaniasis, or Oriental sore (Delhi boil, Aleppo button) can be classified into "wet" and "dry" types. The wet or rural form is

FIG. 221.1 *Leishmania tropica*. Immunization by an induced lesion. (From a nonprofit cooperative endeavor by numerous colleagues under the editorship of Dr. Herman Zaiman, New York.)

caused by *L. major* and is found chiefly in various rodents on the edge of deserts.^{15,44} The dry or urban type is caused by *L. tropica* and is transmitted by phlebotomine species that frequently feed on humans and dogs. The dry or urban form of Oriental sore has a long incubation period, long duration of active infection, and large numbers of parasites in the dermis. The moist or rural type has a short incubation period, with rapid healing and few parasites in the skin. *L. aethiopica* is restricted to the mountain valleys of the Rift Valley of Ethiopia and Kenya, where rock and tree hyraxes are infected regularly. Humans become infected when they intrude in these areas. This form of CL is usually self-limited, although in a small number of individuals (1 per 100,000), nonhealing diffuse cutaneous (DCL) disease has been reported.⁶⁶

Pathology

At the bite site, promastigotes are engulfed by histiocytes, in which they multiply. The histiocytes are destroyed, and amastigotes are released into tissues, where the process is repeated. Lymphocytic and plasma cell infiltration along with histiocytic hyperplasia occurs, and in some lesions, epithelioid and giant cells may be seen. Hypertrophy of the stratum corneum and hyperplasia of dermal papillae occur early, usually followed by necrosis of the area caused by capillary obstruction and endothelial proliferation. The epithelium overlying the center of the lesion becomes necrotic and is sloughed, with the formation of a characteristic ulcer. Secondary neutrophil infiltration also occurs. At this point, a depressed ulcer with a raised purpuric indurated border and a base of friable granulation tissue is present. Amastigotes are located within the cells, although during the period of necrosis, organisms may be seen outside cells but division does not occur.

With *L. tropica*, development of the cutaneous lesion may take weeks to months, with large numbers of parasites present in nests of macrophages. In *L. major* infection, the onset is rapid, with an outpouring of lymphocytes and plasma cells; parasites are sometimes difficult to find. In some cases, satellite lesions form close to the primary lesion so that local spread is seen. The pathologic reaction may be florid, with marked pseudoepitheliomatous hyperplasia that can be mistaken for carcinoma. Secondary bacterial infection may complicate the lesion and delay healing. Once the ulcer heals, however, usually by fibrosis, the patient has long-lasting immunity (Fig. 221.2).

Several manifestations of CL have been described and seem to be associated with the ability of the patient to respond to the infection by cell-mediated immune mechanisms. Whether these mechanisms are directly responsible for protection in humans is still not certain. However, in a small number of patients, the inability to mount a suitable cell-mediated immune reaction is associated with specific anergy to leishmanin and an indolent nonhealing lesion.³⁵ This condition is known as DCL, or diffuse cutaneous leishmaniasis. Characteristically, lesions in DCL are

FIG. 221.2 (A) Typical cutaneous leishmaniasis ulcer. (B) Healed cutaneous leishmaniasis ulcer.

filled with large, parasite-containing histiocytes, and lymphocytes are absent. Recent studies of DCL from the Dominican Republic suggest that immune suppression plays an important role in this form of the disease.

At the other extreme is a small group of patients whose cell-mediated immune response to infection with leishmanial organisms is exaggerated and whose lesions heal by scarring. At the edge of the scar, however, new lesions appear, so the disease seems to extend from the margins. Eventually, tissue damage may be rather extensive. On histologic examination, many lymphocytes, plasma cells, epithelioid cells, and large multinucleated giant cells are seen. Organisms are difficult to locate but sometimes can be cultured from these lesions. This form of CL is called leishmaniasis recidivans. Patients exhibit marked delayed hypersensitivity to leishmanin. Cutaneous leishmaniasis may represent a spectrum of diseases analogous to leprosy.⁶³ DCL is at one end of the spectrum and represents anergy, and leishmaniasis recidivans is at the other end and represents marked delayed hypersensitivity; an ordinary Oriental sore represents the center of the spectrum.

Clinical Manifestations

The disease usually begins with the appearance of a pruritic, red, vesicular papule that appears weeks to months after the bite of a sandfly. The papule gradually enlarges, often measuring 1 to 2 cm in diameter. When the surface of the papule dries, it encrusts and drops off to reveal a shallow ulcer. The ulcer may or may not enlarge progressively and characteristically has raised, sharp, indurated, deep purpuric margins. Healing usually occurs in 3 to 18 months, with an obvious hypopigmented or hyperpigmented depressed scar frequently remaining (Fig. 221.3). However, single or multiple papules often heal directly without extensive ulceration. If the lesions do not become infected secondarily, usually no complications occur.

Diagnosis

Definitive diagnosis depends on demonstrating the amastigotes in tissue specimens or the promastigotes in culture. Microscopic examination of Giemsa-, Wright-, or other rapid blood-stained smears of tissue obtained from nonnecrotic areas of the ulcer or from the base should be performed. Aspiration and culture of tissue fluid taken from the ulcer margin can be positive; however, biopsy material taken from the edge of the ulcer is preferred and should be examined histologically, as should small fragments macerated in saline and inoculated into NNN medium or Schneider's insect medium supplemented with antibiotics. It is very important to make sure the lesion is cleaned thoroughly to remove all secondary infectious organisms (contaminating bacteria and/or fungi) prior to taking the punch biopsy specimen for culture. The specimen of choice would be a collection of several punch biopsy specimens taken from the most active lesion areas. Clinically, the lesions are often characteristic, so the diagnosis should be suspected in a patient who has visited an endemic area.

Although the leishmanin test is usually positive in patients with ulcerated lesions, the material is not readily available in the United States. However, a positive leishmanin skin test may help distinguish a variety of skin lesions such as syphilis, tropical phagedenic ulcer, yaws, tuberculosis, and various fungal diseases. The indirect fluorescent

FIG. 221.3 Healing cutaneous leishmaniasis in a patient from Venezuela.

antibody test or direct agglutination test may be positive in this infection, although often at low titer and, therefore, of little value.

Treatment

Uncomplicated *L. tropica* lesions generally respond well to chemotherapy or to conservative management. Because Old World CL usually remains a local lesion, if the ulcer is not disfiguring and appears to be healing, allowing the lesion to heal spontaneously is appropriate. In most cases, systemic therapy with stibogluconate sodium is effective.³⁷

Ambisome (liposomal amphotericin B) has been used for treatment of visceral leishmaniasis, and more recently for treatment of cutaneous leishmaniasis.³² However, a healthy 38-year-old man treated with liposomal amphotericin B for cutaneous leishmaniasis acquired during military duties in Iraq reported memory difficulties and confusion after completion of his therapy. Extensive evaluation revealed no other source, and his cognitive issues were attributed to liposomal amphotericin B toxicity (mentioned in the package insert). The patient's symptoms resolved over a few weeks, which is consistent with published data about the drug's tissue penetration and metabolism. This is a potential side effect of liposomal amphotericin B that can be observed in otherwise healthy patients.³²

Various imidazoles (e.g., ketoconazole, itraconazole) have been used and appear to have limited antileishmanial activity. An ointment containing paromomycin (aminosidine) and methylbenzethonium chloride (Leshcutan) has been reported to show some promise in treating cutaneous lesions, especially in Israel.^{12,63}

A 31-year-old man who had suffered since age 3 years from diffuse cutaneous leishmaniasis (DCL), a disease with profound physical and psychosocial repercussions and no effective treatment at present, was treated with miltefosine.⁷⁰ The patient was treated for 120 days, 100 mg/day for 1 week, then 150 mg/day subsequently. Lesions were free of parasites at 43 days, and no signs of infiltration were present at day 76. No adverse side effects were observed. The dramatic clinical effect of miltefosine in this patient appears to fully justify further evaluation of this experimental therapy in DCL.

FIG. 221.4 Chiclero ulcer *Leishmania (mexicana) mexicana*. A typical chronic lesion of the external ear is evident. Such lesions never metastasize.

Prevention

Residual spraying for sandflies, eradication of reservoir hosts, and vaccination procedures have reduced and limited this disease in many areas of the Middle East and central Asia. Because of the indolent nature of the healing with vaccination and the possibility of visceralization, this practice has been discontinued in Israel. The customary method for controlling leishmaniasis and sandfly bites in Israel involves the spraying of large quantities of residual insecticides on walls of houses and neighboring surfaces. However, the high summer temperatures, strong radiation, and dust limit the efficacy of the method.²⁰

AMERICAN CUTANEOUS LEISHMANIASIS

The epidemiology and etiology of American CL are quite complex. In South and Central America, many varieties of leishmaniasis exist, including the mucocutaneous form, or espundia. In contrast to Old World CL, American cutaneous disease is tied closely to the forests of South and Central America, and each variety has its own distinct epidemiologic, pathologic, and clinical picture.^{33,35} Whether designating each of the clinical types of American CL by a separate species of *Leishmania* is justified remains unclear. With regard to the American cutaneous forms, two main groups of organisms are distinguished: the *L. mexicana* and *L. braziliensis* complexes (Figs. 221.4 and 221.5). The former are often characterized by rapid growth in culture medium and in hamsters, and the latter are organisms that grow slowly in culture and hamsters. These cases occur from the southern United States to the southern part of Argentina.

Leishmania Mexicana Complex

L. (mexicana) mexicana is transmitted by species of sandflies of the genus *Lutzomyia* (Fig. 221.6). Many rodent reservoir hosts exist. This species is found in Mexico, Guatemala, and Belize. It causes mild infection, often a single cutaneous lesion that is self-limited, or persistent chronic ear lesions, as well as chiclero ulcer.⁴ One case of disseminated disease has been reported. This species is probably responsible for the occasional cases of CL and ATL found in the southern portion of the United States. The range of endemic infection has now been expanded within the United States to include areas that are farther north than the southern Texas site previously identified.^{25,69} Apparently, wood rats serve as the primary wild reservoir hosts in these two states.

Cutaneous leishmaniasis is endemic within south-central Texas and appears to be spreading northward into the Dallas–Fort Worth metropolitan area, affecting humans, cats, and dogs. Multiple vectors and

FIG. 221.5 Mucocutaneous leishmaniasis: *Leishmania (braziliensis) braziliensis*. The entire nasal septum has been eroded. Few organisms could be found by smear or biopsy; however, promastigote forms were cultured from the lesion.

FIG. 221.6 Sandfly.

rodent reservoir hosts exist within Texas; vector-borne sandfly-based transmission is probably the primary means of disease spread in this area. Because of poor surveillance and infrequent diagnosis in the United States, leishmaniasis may have been present within at-risk canine and feline populations before the more recently recognized “outbreaks” in foxhounds or people. Evidence suggests that this disease may continue to emerge as a result of changes in the environment and closer contact between pets and sylvatic ecosystems.^{55,69}

L. (mexicana) amazonensis is found along the Amazon basin and in Trinidad. It rarely infects humans but is transmitted by various species of *Lutzomyia* in rodents. In humans, it causes a mild and self-limited skin lesion. Reportedly, disseminated disease occasionally develops.³⁴

Leishmania Braziliensis Complex (Mucocutaneous Leishmaniasis)

L. (braziliensis) braziliensis or *L. (Viannia) braziliensis* is transmitted by various species of *Lutzomyia* in Brazil and the forest areas east of the Andes. It was originally described by Gaspar Vianna in Brazil as the cause of Bauru ulcer.¹⁹ This organism is the “prototype” of American CL/ATL or MCL, or espundia. It may cause destructive ulcerative lesions of the naso-oropharynx as a result of early or late metastases from a more superficial site.

L. (braziliensis) guyanensis is transmitted by species of *Lutzomyia* in Guyana, Suriname, Brazil, and Venezuela. It causes single or multiple spreading cutaneous ulcers over many parts of the body and is believed to metastasize along the lymphatics but does not visceralize. The organism sometimes spreads to the naso-oropharynx and causes mucosal disease. It sometimes is referred to as pian bois, or forest yaws.

L. (braziliensis) panamensis is transmitted by species of *Lutzomyia* in Panama and possibly farther north and south. It may cause single

to several superficial ulcers and may metastasize along the lymphatics to the naso-opharynx. A cluster of five cases was reported of CL with *L. (Viannia) panamensis* among men attempting emigration from East Africa, who acquired the infection while traveling from Central America to the United States. Species identification of the infecting species revealed important information related to a well-defined human smuggling route with potential public health consequences from this emerging infectious disease risk.¹³ High rates of *L. (braziliensis) panamensis* have been found among Cuban immigrants trafficked through the Darien jungle, Panama.⁶

L. (braziliensis) peruviana is seen in Peru on the western slopes of the Andes to an altitude of 3000 m. It causes a single or a few self-healing ulcers. No oronasopharyngeal spread occurs. Often, it is referred to as uta. Dogs are regarded as the reservoir hosts.

In MCL as represented by espundia, researchers estimate that nasal involvement may occur in as many as 80% of infections, up to 30% of which eventually mutilate the mucous membranes of the mouth, nose, palate, larynx, and trachea. These cases are often fatal because of the intervening sepsis. Lesions of the mucous membranes often occur years to decades after a cutaneous ulcer has healed. Once mucous membrane involvement occurs, the infection may be difficult to cure using chemotherapy.

Diagnosis

The discussion of Old World CL includes the various methods for diagnosis. In mucocutaneous disease, the fluorescent antibody test using amastigote antigen is most useful in that it is positive in 75% to 85% of cases, with declining titers after therapeutic cure.³⁵ A direct agglutination test using promastigotes also is used frequently, as is enzyme-linked immunosorbent assay (ELISA).³⁵ A DNA-DNA hybridization or dot-blot test that is highly sensitive and species-specific in tissue or biopsy specimens has been used.⁴⁷ Isozyme analysis of isolated organisms currently is being used to help identify the species causing the infection.

Treatment

As in Old World CL, treatment of most lesions is effective using pentavalent antimonials. Because prompt and adequate therapy for primary cutaneous lesions may reduce the risk of subsequent metastatic disease in potentially mucocutaneous infections, pentavalent antimony should be used. If lesions should prove unresponsive to antimony therapy, amphotericin B should be tried. Liposomal amphotericin treatment has been useful in selected studies.¹⁷ Relapses with this form of leishmaniasis are common and must be retreated. Pentavalent antimonials are moderately effective in treating mild mucosal disease but are often unsatisfactory with severe mucosal involvement. Diffuse cutaneous leishmaniasis, a disseminated form of the disease, should be treated with stibogluconate sodium³⁷; when relapses occur, amphotericin B should be used next because this disease is usually refractory to further antimony therapy.^{17,35} Pentamidine also has been used with limited success when lesions have proved resistant to antimony compounds. Pentavalent antimony-resistant cutaneous disease, such as leishmania recidivans, has been treated with limited success with ketoconazole, 400 to 600 mg daily for 4 weeks. Miltefosine, an oral antileishmanial agent effective against VL, has shown promise for the treatment of ATL (*L. panamensis/amazonensis*).¹⁶

Prevention

This disease is extremely difficult to prevent because it is a forest disease. It can be avoided only by sleeping in tents under fine-mesh netting, wearing long-sleeved clothing, and using insect repellents. The presence of *Leishmania* parasites in the unaffected skin and peripheral-blood monocytes of a high proportion of patients even after treatment and the acquisition of infection by sandflies supports the plausibility of anthroponotic transmission of American cutaneous leishmaniasis.⁶⁸ As travel to Latin America has become increasingly common, cutaneous leishmaniasis is increasingly seen among returning travelers—for instance, the number of observed cases has doubled in the Netherlands and tripled in the United Kingdom in the past decade.⁶² A high proportion of cases are acquired in rural or jungle areas of the Amazon basin. In children acquiring cutaneous *Leishmania (Viannia) braziliensis* infections,

the major risk factor for acquisition of disease was the presence of an adult in the household with cutaneous leishmaniasis within the previous year.³ Humans may serve as both reservoir and source of infection for young children. Vaccine development against American cutaneous leishmaniasis is underway.^{38,56}

VISCERAL LEISHMANIASIS

VL is caused by various organisms in the *L. donovani* spp. complex in Asia and Africa, as well as by *L. infantum* in southern Europe and North Africa and the related *L. chagasi* in Brazil and elsewhere in the new world. Strains of *L. tropica* from the Middle East and *L. amazonensis* from Latin America have also been found to cause this syndrome.⁴³

VL, or kala-azar, is found in a broad belt that extends from the Strait of Gibraltar across the Mediterranean through Asia to the east coast of China, at latitude between 30 and 48 degrees north. It is transmitted by various species of sandfly, although congenital and blood-borne infections can also occur.⁴⁵ VL has been reported from 47 countries, but the Sudan and India account for more than half of cases. In the Western Hemisphere, it is found in Brazil, northern Argentina, Paraguay, Venezuela, Colombia, Guatemala, and Mexico. Kala-azar appears to exist in at least three epidemiologic forms.

The Mediterranean type of VL, with a canine reservoir, infects young children (1 to 4 years of age); dogs, foxes, or feral animals are the reservoirs (*L. infantum*). This type extends from the Mediterranean littoral through central Asia into China; it is also present in parts of South America (*L. chagasi*), where foxes and dogs are reservoir hosts. In Brazil, young males are infected most often. Infected dogs are the primary reservoir for zoonotic visceral leishmaniasis in endemic regions and are the most significant risk factor predisposing humans to infection.⁵⁵ Dogs have a wide range of clinical presentation due to infection with *L. infantum*, ranging from asymptomatic to fatal visceral disease.

An Indian type (*L. donovani*) of VL with a human reservoir predominates in Indian children between 5 and 15 years of age; humans are the only known reservoir. Though sought, evidence of natural infection in dogs has not been found. No evidence of rodent reservoirs exists.

The African type of VL has rodents for the reservoir hosts. The Nile rat in the Sudan and probably the gerbil in Kenya are the reservoirs. In Kenya, researchers have noted that kala-azar often is related to old or eroded termite mounds where young males often congregate (see Fig. 221.5).

Pathology

The main pathologic lesions are the result of reticuloendothelial cell hyperplasia, especially in the spleen and liver (Fig. 221.7). Later, the bone marrow and lymph nodes are filled with infected macrophages, and a concomitant leukopenia and anemia develop (i.e., pancytopenia). Also, the kidneys may be filled with infected macrophages, and invasion of the submucosa and mucosa of the duodenum and jejunum results in hypertrophic congested and edematous villi. Small ulcerations and hemorrhages may occur. The spleen gradually enlarges, sometimes assuming enormous proportions, and eventually extends into the pelvis. Splenic infarcts are a frequent development. The capsule is thickened, and more deeply, the sinuses are dilated. Erythrophagocytosis by histiocytes is seen commonly, and the anemia so typical of kala-azar may in part be the result of such sequestration of red cells. Kupffer cells of the liver, filled with amastigotes, are swollen and hyperplastic, and centrilobular necrosis or fatty infiltration of the hepatic parenchyma often is observed. In late-stage or chronic disease, increased hepatic fibrosis may give a nodular cirrhotic appearance. Lymphadenopathy, especially of the mesenteric glands, is an early finding, and large numbers of parasite-filled macrophages are present. The bone marrow often is filled with parasitized histiocytes that replace the normal marrow elements; such replacement results in myelophthisic anemia.

The immunologic response to kala-azar infection is imperfectly understood. At the bite site, a small, pea-sized, dermal lesion may form (i.e., a leishmanioma); the parasites, initially localized in dermal macrophages, disseminate within the macrophages to the spleen, liver, bone marrow, and lymph nodes.

FIG. 221.7 (A) *Leishmania tropica* in a macrophage. The red arrow indicates the nucleus in the amastigote; the black arrow indicates the kinetoplast (small bar). (B) *Leishmania donovani* in a liver touch preparation.

The infection outcome depends on the host's ability to raise a suitable cell-mediated immune response and the virulence of the invading organism. Experimentally, resistance in mice appears to be determined by a single autosomal gene. Researchers have shown in experimental infections that the disease is controlled by the T_H1 subset of $CD4^+$ and $CD8^+$ T cells; these cells are related to the production of cytokines such as interferon- γ (IFN- γ), interleukin-2, and tumor necrosis factor- α . Infection with *L. donovani* amastigotes induces a T_H1 cytokine milieu in both dendritic cells and T cells.³¹ Cytokines activate macrophages to kill intracellular amastigotes by oxidative and nonoxidative mechanisms. Studies in mice indicate that nitric oxide is an important factor in killing amastigotes. If the infection is not eliminated or controlled by the host's cellular immune response, it then becomes clinically evident. Lymphocytogenesis and histiocytogenesis occur in affected organs, with resultant hepatosplenomegaly and lymphadenopathy. Polyclonal B-cell activation ensues and causes hyperglobulinemia. This outpouring of humoral antibodies, chiefly IgG and largely nonspecific, is not protective and may represent more than half the total serum proteins of the patient. The specific antibodies produced during active disease have diagnostic significance. Fluorescent antibody, ELISA, indirect hemagglutination, and complement-fixation tests are reasonably reliable diagnostic procedures.

Resistance to kala-azar is essentially absent once the infection has become evident clinically. However, after chemotherapeutic cure, acquired immunity emerges; delayed hypersensitivity, as demonstrated by the Montenegro (leishmanin) skin test (see later), also becomes apparent. Moreover, the hypergammaglobulinemia abates concomitant with chemical cure and the appearance of delayed hypersensitivity. Usually, immunity to VL is complete and long lasting after chemotherapeutic cure. However, relapse, as seen in post-kala-azar dermal leishmaniasis (PKDL), is characterized by delayed hypersensitivity, dermal localization of parasites, and moderate hypergammaglobulinemia. Although macrophage activation results in enhanced phagocytosis of parasites, macrophages remain unable to eliminate parasites. The appearance of dermal delayed hypersensitivity at the time that acquired immunity appears suggests that cell-mediated immunity plays an important role in protection. Further work on this aspect of VL is needed. The genetics of resistance in humans remains unclear.

Clinical Manifestations

The incubation period varies widely from 6 weeks to 6 months but has been reported to be as short as 10 to 14 days and as long as 10 years. A primary skin nodule is rarely seen, although in African leishmaniasis, it is a more regular feature. Infantile VL may begin either suddenly with high fever and vomiting or insidiously with irregular daily fever, anorexia, weight loss, lassitude, and pallor. When fever is present, double daily spikes are a characteristic sign, with temperatures reaching 40° to 40.6°C.

The spleen gradually enlarges so that by the end of the first month, it can be palpated. If the symptoms continue unabated, the spleen may extend to the umbilicus or even into the pelvis. Diarrhea or frank dysentery is not unusual, and blood sometimes is observed. A general bleeding diathesis often becomes evident shortly before death. After several months, if the disease is untreated, patients usually die. Acute fulminant disease is seen more often in infants and young children.

In other cases, the clinical course is more protracted and generally ends fatally after a year or two. In older age groups, the disease tends to assume a more chronic course, with marked emaciation, brittle hair, massive splenomegaly, lymphadenopathy, and a dusky slate-gray complexion. Hyperglobulinemia, leukopenia, and anemia typically are found. As a result of general debility, death often results from concurrent infections such as pneumonia, amebic or bacillary dysentery, malaria, or cancrum oris in more than 90% of cases. Infantile VL has been associated with alterations in lipoprotein metabolism.⁷ A handful of cases of presumed congenital VL have been reported.²⁶ These infants were born of infected mothers, and in some, evidence of parasitism of the placenta was found.²⁶ However, whether these cases represent congenital infection or peripartum infection is unclear because sophisticated serologic techniques were not available.

Infantile visceral leishmaniasis in the Mediterranean basin may begin with a high fever and vomiting or with irregular daily fevers, anorexia, and splenomegaly. In a small group of patients, an unusual echographic pattern of multiple nodules associated with splenomegaly was reported.⁴⁸ The authors strongly suggested that splenic nodules may represent a signature finding in infants.

In another pediatric study reviewing characteristics of visceral leishmaniasis-associated hemophagocytic lymphohistiocytosis (HLH), disease onset occurred before age 2 years and the symptoms could not be distinguished from other HLH causes. With therapy, 11 of 12 patients had a long-term remission. Several cases were treated with prolonged L-AmB therapy.¹¹

In a study of hormonal disturbances in visceral leishmaniasis, primary adrenal insufficiency was observed in 45.8% of patients; low aldosterone/renin plasma ratio in 69.4%; low daily urinary aldosterone excretion in 61.1%; and low transtubular potassium gradient in 68.0%. All patients had normal plasma antidiuretic hormone (ADH) concentrations, hyponatremia, and high urinary osmolality. Plasma parathyroid hormone was low in 63%; hypomagnesemia was present in 46.4%, and increased urinary magnesium excretion in 100%. Primary thyroid insufficiency was observed in 24.6%, and secondary thyroid insufficiency in 14.1%. Normal follicle-stimulating hormone plasma levels were present in 81.4%; high luteinizing hormone and low testosterone plasma levels were found in 58.2% of men. There were also hypothalamus-pituitary-adrenal axis abnormalities, inappropriate aldosterone and ADH secretions,

and presence of hypoparathyroidism, magnesium depletion, and thyroid and testicular insufficiencies.⁶⁷ Patient ages ranged from 15 to 58 years.

Cutaneous manifestations of kala-azar are encountered frequently. In India, the dark gray appearance of the skin is known as kala-azar (black sickness). In some cases of inadequately treated VL, PKDL may ensue. In Indian VL, this complication is encountered in 15% to 20% of cases and appears several years after therapy. Individuals with kala-azar and individuals with PKDL are considered to be reservoirs of transmission of *L. donovani* in India.⁶⁴ In African disease, PKDL occurs much less commonly, often during therapy in approximately 2% to 3% of cases, and it heals spontaneously in a few months. The lesions are characterized by the appearance of hypopigmented, erythematous, or nodular lesions on the skin of the face, chest, neck, and buttocks. At times, the nodular lesions of the face may resemble lepromatous leprosy. The lesions are thought to represent a modified form of *L. (L.) donovani* infection in which the parasites no longer invade the viscera and are localized to the skin. These lesions seem to be related to the host's immune response. This change to dermal tropism is said to coincide with recovery from visceral disease and to disappear with relapse. Infection with *L. (L.) chagasi* causes VL in young children. Atypical CL has been reported in older children with this infection.⁸

Pancytopenia is not unusual. Characteristically, anemia is always evident, with hemoglobin levels below 8 g/dL. Survival of red cells is shortened as a result of several possible factors, including Coombs-positive hemolytic anemia and hypersplenism. Leukopenia of 2000 to 3000 cells/mm³ typically is found with neutropenia, relative lymphocytosis, an almost total absence of eosinophils, and thrombocytopenia. Serum albumin is usually less than 3 g/dL, and globulin levels (mostly IgG) are often greater than 5 g/dL (5 to 10 g/dL).

Kala-azar has been reported as an important opportunistic infection in patients infected with human immunodeficiency virus type 1 (HIV-1) and not known to have contracted *Leishmania* infection previously. These patients appear to have a more severe and fulminant form of kala-azar. In this regard, inapparent *Leishmania* infection may become evident after immunosuppression, such as chemotherapy for malignant disease. The diagnosis may be particularly difficult to make, inasmuch as the findings are often atypical and consist of low-grade fever, fatigue, cough, and gastrointestinal complaints. Certainly in AIDS patients, VL is a recurrent disease that is highly prevalent and whose clinical course is modified by HIV. VL is very prevalent among HIV-1-infected patients in southern Spain, with a high proportion of cases being subclinical.¹ Symptomatic cases appear mainly when severe immunosuppression is present. There is also an association between VL, the male sex, and intravenous drug use. Similarly, atypical visceral disease caused by *L. tropica* was seen in individuals who participated in Operation Desert Storm in the Persian Gulf.⁴²

Diagnosis

VL is diagnosed by finding the organism in stained smears of spleen aspirate,²⁷ peripheral blood, or bone marrow (Fig. 221.7). In Indian kala-azar, the parasites may be found regularly in peripheral blood monocytes (i.e., buffy coat), but in the African and Mediterranean forms, they may be difficult to find by this technique. Blood and marrow cultures grown on NNN medium or in Schneider insect medium with 15% to 20% fetal calf serum are most useful (Fig. 221.8). Some investigators regard splenic rather than bone marrow aspiration as the most sensitive procedure, although it can be especially hazardous in individuals with a bleeding diathesis. Contraindications include a soft or diffident, acutely enlarging spleen. Patients with low platelet counts or a prolonged prothrombin time (or both) should not undergo the needle biopsy procedure. In children younger than 5 years, splenic aspiration should be performed only by a physician fully experienced in the procedure.

Spleen and bone marrow aspirates should be placed in culture medium and smeared on slides, and saline-diluted aspirates should be inoculated into the peritoneal cavity of hamsters (see Fig. 221.6).

In a study conducted in pediatric patients in the Mediterranean region, antibody detection techniques, the antigen detection in urine (KAtex kit), and *Leishmania* nested PCR (LnPCR) analysis of the blood were useful for diagnosis of the first clinical episode.¹⁸ After treatment, clinical improvement was associated with negative NNN cultures and

FIG. 221.8 *Leishmania* sp. promastigotes from culture system.

microscopy of bone marrow aspirate, KAtex test, and LnPCR blood analysis results. New noninvasive techniques tested showed high diagnostic sensitivity. However, LnPCR analysis of the bone marrow was the most sensitive and was able to detect the persistence of parasites and predict potential relapses.¹⁸

Diagnostic approaches for visceral leishmaniasis have been improved in the past decade with the development of serological and molecular tests. However, in many parts of the world, a definitive diagnosis still relies on the older parasitological methods. Recombinant antigens have led to improved performance of serodiagnostic methods. Serology-based tests, rk39 antigen dipstick, and direct agglutination test are highly sensitive methods; however, they fail to distinguish present from past infections. Molecular approaches have become increasingly relevant because of their remarkable sensitivity, specificity, and flexibility in sample selection. Quantitative PCR is a highly sensitive and specific tool used in referral labs for detection and assessment of parasite load in VL patients and in monitoring treatment response. This method has the potential to distinguish asymptomatic patients in endemic areas. Techniques such as loop-mediated isothermal amplification offer a reliable molecular diagnostic method for field application.^{59,65}

Nonspecific tests detecting the markedly elevated serum globulins, such as the formol gel test, are helpful in acute disease and are performed readily in the field. Antileishmanial antibodies are usually present and can be used to aid in the diagnosis. The fluorescent antibody test is highly specific, as are the indirect hemagglutination and gel diffusion tests. The complement-fixation test, however, is positive in only 65% to 70% of cases. Sera from patients with VL are known to give false-positive results when antibodies to *T. cruzi* are present; consequently, in the Western Hemisphere, absorbing out these antibodies may be necessary. It is important to recognize that fluorescent antibody titers usually fall after complete cure, so a negative titer often is regarded as a sign of successful therapy. DNA-DNA hybridization tests are being evaluated and promise exquisite specificity and sensitivity for the diagnosis of leishmaniasis.⁴⁷ Serologic tests may be positive as a result of past or subclinical inapparent infection. An ELISA that detects antibodies to a cloned recombinant antigen, K39, of *L. chagasi* has been shown to be specific in active VL and could detect antibodies in AIDS patients. A recent study has demonstrated that this test could be applied to field situations.

In HIV-1-infected patients with active VL, the sensitivity of a peripheral blood smear is about 50%, because of a high parasitemia in these patients. However, in patients with HIV-1 and subclinical VL, the sensitivity of a routine blood smear is less than 10%.¹ Unfortunately, in these patients serology and *Leishmania* skin tests have low sensitivities and are not very helpful. Cultures have proven to be effective in VL patients who are coinfecting with HIV-1. The usual diagnostic tests may also be negative in patients with *L. tropica* infection or in otherwise profoundly immunocompromised patients. However, two genomic

fragments encoding portions of a single 210-kDa *L. tropica* protein have proved useful for the diagnosis of viscerotropic *L. tropica* infection in Desert Storm patients.²⁴

The leishmanin or Montenegro skin test, like the lepromin and tuberculin skin tests, is a measure of delayed hypersensitivity to leishmanial antigen. It consists of 10⁶ phenol-killed, culture-grown promastigotes in 1 mL of 0.5% phenol in saline. The test is performed like the tuberculin test, that is, 0.1 mL is injected intradermally. A positive result is a palpable area of induration at least 5 mm in diameter in 48 to 72 hours. Because the leishmanin test can be positive in CL or VL, the results must be evaluated carefully. In VL, the test remains negative throughout the period of active disease. Once chemotherapeutic control starts to take effect and immunocompetent lymphocytes are able to respond, the test begins to turn positive.¹⁴ Thus, recovery from kala-azar is characterized by the development of cell-mediated immunity. The change from a negative to a positive leishmanin test in VL is regarded as an important prognostic sign that protective immunity is developing or has developed. Because numerous reports noting positive leishmanin tests in individuals who have had no history of VL have appeared, researchers have postulated that many individuals in an endemic area may become immune by previous inapparent infection.

Prognosis

Untreated VL is fatal in 75% to 85% of infantile and 90% of adult cases. Properly treated at an early stage, it can be cured in 85% to 95% of cases. The prognosis for patients in whom pancytopenia or bleeding diatheses develop or in whom a delayed hypersensitivity skin reaction fails to develop usually is poor.

Patients can be initially misdiagnosed as having an autoimmune disease because visceral leishmaniasis may mimic diseases such as systemic lupus erythematosus, autoimmune hepatitis, dermatomyositis, or other disorders. In pediatric patients, the risk of life-threatening complications is very high; thus, leishmaniasis must be considered in order to avoid an incorrect diagnosis and inappropriate immunosuppressive therapy.⁵¹

Treatment

VL generally responds to treatment with pentavalent antimonials such as stibogluconate sodium (Pentostam, Triostam), which is the usual drug of choice in the United States and is available through the Drug Service of the Centers for Disease Control and Prevention.³⁷ Meglumine antimoniate (Glucantime) is available in French-speaking countries and Latin America.¹⁶ The pediatric and adult dose is 20 mg/kg daily administered intramuscularly or intravenously for 28 days. Treatment can be repeated. In areas where leishmanial parasites may have acquired relative resistance to pentavalent antimonials, such as India, Nepal, and East Africa, extending therapy for more than 4 weeks may be necessary.⁴¹ Side effects occur commonly and include nausea, vomiting, headache, anorexia, and abdominal pain. Elevated levels of serum amylase and lipase, indicative of pancreatitis, are encountered occasionally and can be severe. Electrocardiographic changes are seen, including decreased T-wave amplitude and T-wave inversion, prolongation of the QTc, and nonspecific ST-T wave changes. They resolve shortly after therapy is concluded. (Treatment should be discontinued if the QTc interval exceeds 0.5 second.) Deaths, presumably caused by arrhythmias, have been reported in patients who were receiving more than 20 mg per day. Primary antimony resistance, as well as relapses after receiving pentavalent antimony therapy, occurs with all types of VL but is most often encountered with the Indian form. The mechanism of antimonial resistance is unclear. In HIV-infected patients, almost 25% fail to respond to antimony therapy, and almost 40% of responders subsequently relapse.^{49,54}

Liposomal amphotericin B (AmBisome) has been approved by the US Food and Drug Administration for the treatment of VL. This compound is taken up by cells of the reticuloendothelial system, where amastigotes reside, and is less nephrotoxic, thereby allowing for higher daily doses with shorter courses of therapy. The approved, recommended regimen for immunocompetent VL patients is 3 mg/kg per day on days 1 through 5 and days 14 and 21. In immunosuppressed and HIV patients, treatment of VL with AmBisome has resulted in an almost 100% response rate. However, most of these patients relapse.^{49,54} The recommended treatment is 4 mg/kg per day on days 1 through 5, 10, 17, 24, 31, and

38. Without maintenance therapy, almost all these patients relapse. Because resistance to pentavalent antimonials has developed, amphotericin B is used and is highly efficacious. Several recent studies have used liposomal amphotericin B successfully for the treatment of VL presumably caused by *L. infantum* in immunocompetent children.³⁵

Parenteral pentamidine isethionate (Pentam 300) is administered intramuscularly (4 mg/kg is given three times weekly for up to 15 doses, depending on side effects such as hypotension, vomiting, and blood dyscrasias). Pentamidine occasionally may exacerbate diabetes mellitus or precipitate latent diabetes. Shock and liver and renal damage have been reported.

In several clinical trials, miltefosine, an oral alkyl phospholipid agent initially developed as an oral antineoplastic drug, has been used as an effective agent for the treatment of antimony-resistant Indian VL.^{9,39} The treatment dose was 2.5 mg/kg per day for 4 weeks.

Patients may require hospitalization for therapy; supportive and corrective measures should be instituted in the event that other infections are present. An occasional patient may be encountered who may require splenectomy to relieve the profound hypersplenism and the resulting anemia. Response to therapy often can be assessed by return of the patient's temperature to normal, a brisk reticulocytosis, a gradual reduction in spleen size, and the reappearance of eosinophils on the peripheral blood smear.

Allopurinol has been used with pentavalent antimonials to treat cases of VL that did not respond to pentavalent antimonials alone. Several reports suggest that recombinant IFN- γ is helpful, along with pentavalent antimonial drugs, in successfully treating this disease. Because assessing whether a cure has been achieved is difficult, patients must be monitored at 6-month intervals for as long as 2 years. Fluorescent antibody titers should be absent by the end of 1 year and complement-fixation titers by 6 to 8 months. If PKDL occurs, treatment should be reinstituted.

Prevention

Control of VL has many aspects. Sandflies (*Phlebotomus* and *Lutzomyia*) can be eliminated readily by residual spraying. Because sandflies ordinarily do not fly very high, sleeping quarters should be above ground level. Permethrin-impregnated bed nets can be highly effective in preventing sandfly bites. Animal reservoirs, such as infected dogs and rodents, should be destroyed. Early therapy will prevent family and neighborhood transmission. A vaccine against different forms of leishmaniasis should be feasible, considering the wealth of information on genetics and biology of the parasite, the clinical and experimental immunology of leishmaniasis, and the availability of vaccines that can protect experimental animals against challenge with different *Leishmania* species. At the present time, however, there is no vaccine for human use against any form of leishmaniasis.³⁸ One major obstacle is the lack of a conceived market for human leishmaniasis vaccines. Ninety per cent of visceral leishmaniasis occurs in five countries (Bangladesh, Brazil, India, Nepal, and Sudan). Nonetheless, local studies for vaccine development are ongoing in India and Brazil.

Trypanosomes are protozoan parasites that are widely distributed in nature.¹²¹ They are found in a broad range of cold- and warm-blooded vertebrates, as well as in a large number of invertebrate species that frequently act as vectors.⁸⁷ It is fair to say that if an animal has blood or a blood-like substance, it is likely that it acts as a host for trypanosomes. The striking diversity of animals infected with trypanosomes suggests that these parasites may confer a survival advantage to their hosts. Trypanosomes were first seen by Valentin, who in 1841 saw them through a microscope in the blood of a trout. Shortly thereafter Gluge and Gruby saw trypanosomes in toad blood and, upon observing their undulating membranes, named the genus *Trypanosoma* (Greek: *trypanon* means auger or screw, and *soma* means body). Lewis, while studying rats, was the first to see trypanosomes in mammalian blood, and trypanosomes were first seen in human blood in 1901 by an English boat captain named Forde who was traveling on the Gambia River with a febrile passenger. The following year that organism was named *Trypanosoma gambiense* by Dutton. Around that time sleeping sickness became a defined illness in Africa (today more broadly called human African trypanosomiasis [HAT]), and by 1905 its cause had been found, its vectors had been identified, and the first therapeutic drug (atoxyl) had been found. This remarkable progress resulted from the efforts of a number of investigators, and in recognition of Bruce's prominent role in the process the infecting species was named *Trypanosoma brucei*.¹⁰⁰

Within a few years the Brazilian physician, Carlos Chagas, discovered the cycling of trypanosomes between wild mammals and insect vectors and also observed the organism in the blood of an ill 2-year-old child.^{34,41} Chagas named the organism *Schizotrypanum cruzi* (later renamed *Trypanosoma cruzi* by others) after his mentor Oswaldo Cruz, and the disease ultimately became known as Chagas disease (now also referred to as American trypanosomiasis). Chagas presented detailed descriptions of the organism, its presence in insect and mammalian hosts, and the acute illness it can cause in humans in a monumental publication in German in 1909.⁴¹

Only three species of trypanosomes infect humans. The first is *Trypanosoma rangeli*, which is endemic in areas of Central and South America, does not appear to cause persistent infection, and is not known to be pathogenic. *T. cruzi* has a much larger endemic range, including Mexico as well as all the countries of Central and South America, establishes lifelong infection, and is a major cause of morbidity and death in humans. Two subspecies of *T. brucei*, *T. b. gambiense* and *T. b. rhodesiense*, which are endemic in West and East Africa, respectively, also cause persistent infection and often result in serious illness and death in infected persons. In areas endemic for Chagas disease or HAT, children are at risk for becoming infected. Despite the similarity of the organisms that cause Chagas disease and HAT, they are quite different when viewed from biologic, epidemiologic, and clinical perspectives and thus are considered separately in this chapter.

AMERICAN TRYPANOSOMIASIS (CHAGAS DISEASE)

Biology, Life Cycle, and Mechanisms of Transmission of *Trypanosoma cruzi*

American trypanosomiasis, Chagas disease, and *T. cruzi* infection are synonyms and simply indicate infection with *T. cruzi*. *T. cruzi* is a single-celled protozoan hemoflagellate parasite (order Kinetoplastida, family Trypanosomatidae) (Fig. 222.1). The molecular tools developed in recent decades have been applied in extensive studies of *T. cruzi* genetics and biochemistry. Notably, the complete sequence of the *T.*

cruzi genome was published in 2005, as were those of the closely related species *T. brucei* and *Leishmania major*.^{18,64,65,94} Molecular work on *T. cruzi* has focused on a broad range of basic and applied issues, including extensive molecular epidemiologic studies. In the latter, genetic analyses of *T. cruzi* isolates from geographically diverse vectors and mammalian hosts, including humans, have shown that there are six lineages, designated TcI to TcVI.¹³⁴ Unfortunately, no crisp associations between the lineages and pathogenicity or drug susceptibility have been found. In general, the extensive genetic and more recently proteomics data generated to date, including the framework of the lineages, have not yet led to new tools to reduce transmission, advances in the management of clinical disease, the development of new drugs, or the development of a vaccine.

In contrast, in the area of diagnosis the results of molecular work on *T. cruzi* has led to advances that directly affect persons at risk for or having *T. cruzi* infection. Application of DNA sequence data, generated for the most part in the late 1980s and 1990s, has led to the development of polymerase chain reaction (PCR) assays for detecting *T. cruzi*.^{140,157,178,193} By far the most important application of these assays is for testing infants born to *T. cruzi*-infected mothers for congenital Chagas disease. In addition, to a limited extent these assays are used for diagnosing other acute *T. cruzi* infections, including reactivation in immunosuppressed persons, and for detecting treatment failure in chronically infected patients. In a second instance, *T. cruzi* molecular data have been productively exploited in the development of serodiagnostic assays for chronic *T. cruzi* infection. Several assays based on recombinant *T. cruzi* proteins are available commercially in the endemic countries and in other areas to which at-risk persons have emigrated (particularly the United States and Europe), and to date tens of millions of persons have been tested accurately with these assays.^{43,47,156}

T. cruzi has a complex life cycle and can infect a variety of mammalian species, both omnivores and carnivores, as well as many species of insect vectors [family Reduviidae (assassin bugs), subfamily Triatominae (kissing bugs or triatomines)] (Fig. 222.2). The vectors are sometimes called reduviid bugs but more correctly should be referred to as triatomines.^{120,191} Notably, the parasites go through distinct developmental stages in both insect and mammalian hosts. Vectors become infected when they take blood meals from mammalian hosts that contain nondividing trypomastigote forms of the parasite (Fig. 222.3). Once in the midgut of the vectors, the trypomastigotes transform into epimastigotes, which then multiply and ultimately move into the hindgut, where they become nondividing infective metacyclic trypomastigotes that are discharged with the feces at the time of a subsequent blood meal. Transmission then takes place to another mammalian host when breaks in the skin, conjunctivae, or mucous membranes (e.g., the nares or oral mucosa) are contaminated with bug feces containing infective forms. The latter can enter a wide variety of cell types, and after doing so transform to amastigotes, which are dividing intracellular forms (Fig. 222.4). The host cells soon fill with dozens of dividing amastigotes and then, likely in response to biochemical stress or specific signals, transform to bloodstream trypomastigotes. These parasites are released as the infected cell ruptures, and they presumably invade adjacent cells or find their way into the lymph and bloodstream and thus spread throughout their host. The vector-borne cycle is completed when circulating parasites end up in a blood meal of a vector.

Other routes of transmission of *T. cruzi* merit mention. Congenital transmission of *T. cruzi* has long been recognized as an important problem. Studies have shown that the overall risk of congenital transmission of the parasite from chronically infected mothers to their infants is about 5%, with a range in various studies of 2% to 10%.⁹⁰ Transfusion

of blood from *T. cruzi*-infected donors can result in transmission of the parasite,^{15,109,180} as can transplantation of organs obtained from infected donors.^{48,38,189} Several outbreaks have been reported of acute Chagas disease caused by ingestion of food and drink contaminated with infected vector excreta or by the insects themselves, and finally dozens of laboratory accidents involving transmission have been described.

Epidemiology

T. cruzi is enzootic from southern Chile and Argentina to the southern tier of states in the United States. In spotty distributions within this range large numbers of at least a dozen species of triatomine insects capable of harboring *T. cruzi* are found,^{77,111} as are large populations

of potential mammalian hosts.^{52,146} *T. cruzi* has been isolated from more than a hundred mammalian species, and armadillos, opossums, wood rats, raccoons, and canines are among those most commonly parasitized. Infected vectors live in the burrows and nesting places of the mammals, and contact with *T. cruzi*-infected feces in such places may be an important mechanism of transmission. Ingestion of infected insects also may be a common means of transmission, and the eating of infected mammals by carnivores may be important as well. Congenital transmission also occurs in these mammalian hosts,⁹ but there is no direct evidence that sheds light on the relative importance of these routes of transmission in the sylvatic cycle. It is fair to say that most *T. cruzi* parasites are in infected wild mammals and insect vectors. Humans and domestic animals are only incidental hosts and have little to do

FIG. 222.3 *Trypanosoma cruzi* trypomastigotes in rat blood smear (Giemsa, $\times 625$). (Courtesy Dr. Herbert B. Tanowitz, New York, NY.)

FIG. 222.4 *Trypanosoma cruzi* amastigotes and trypomastigotes in mouse macrophages in liquid culture. (Courtesy Dr. James A. Dvorak, Bethesda, MD.)

with the long-term persistence of the enormous reservoir of *T. cruzi* in the wild. Given the existence of the wildlife reservoir, the elimination of *T. cruzi* is not a realistic goal. Rather, resolution of the problem of human Chagas disease will result primarily from reducing contact with vectors, eliminating transmission by transfusion and organ transplantation, and treating infants with congenital transmission, and major progress along these lines has been made in recent decades.

The endemic range of Chagas disease includes all the countries of Central and South America as well as Mexico, a total of 21 nations. It is often stated that all of Latin America is endemic, but strictly speaking this is incorrect because there is no Chagas disease in Haiti, Cuba, the Dominican Republic, or Puerto Rico, which certainly are part of Latin America, whereas Belize, Surinam, and Guyana are not part of Latin America but are endemic. There is no Chagas disease in any of the Caribbean islands.

Historically, in the endemic range humans have become involved in the sylvatic cycle of *T. cruzi* transmission when they move into enzootic areas and infected vectors take up residence in the primitive wood, mud, and stone houses that are typical in rural areas. Native Americans who live in enzootic areas typically are affected as well.^{73,125} The massive migrations that have been going on for decades from rural areas with vector-borne transmission to cities, where little if any such transmission occurs, has served to urbanize the disease in a major way. Similarly, Chagas disease has become globalized as many millions of persons from endemic countries have emigrated to nonendemic nations, and increased recognition of the consequent risk of chagasic cardiac and gastrointestinal (GI) disease, as well as congenital transmission, has occurred in these areas as well.^{40,92,129,165,168,187}

The World Health Organization (WHO) estimated that 6 to 8 million persons are infected with *T. cruzi* in the endemic countries, and that

annually about 12,000 deaths can be attributed to Chagas disease.⁴² In addition, estimates have put the number of new *T. cruzi* infections per year at 28,000, of which approximately 15,000 result from congenital transmission.³³ Studies have shown that the overall risk of congenital transmission of the parasite from chronically infected mothers to their infants is about 5%, with a range in various studies of 2% to 10%.⁹⁰

Epidemiologic data have long indicated that most new vector-borne *T. cruzi* infections occur in children. However, children are not known to be intrinsically more susceptible than adults to acquiring *T. cruzi* infection. They become infected early simply because their exposure to infected vectors often begins as soon as they are born. Risk is thought to be simply a function of the likelihood of infective parasites coming in contact with vulnerable host cells, independent of age.

The aggregate economic impact of Chagas disease in the endemic countries has been estimated to be in the range of US\$8 billion per year.^{117,179} When viewed from a global perspective, the death toll attributable to Chagas disease, which is roughly equal to the death toll attributable to intestinal helminths, ranks third among neglected tropical diseases, after malaria and leishmaniasis.¹³⁹

In contrast to this gloomy situation resulting from the prevalence of chronic Chagas disease in the endemic countries, the outlook regarding secular patterns of transmission of the parasite is markedly much brighter. Starting decades ago, vector control programs were quite successful in some areas (e.g., São Paulo State in Brazil). In 1991, moreover, the six countries of the Southern Cone of South America (Uruguay, Paraguay, Argentina, Bolivia, Chile, and Brazil), in cooperation with the WHO and the Pan American Health Organization, began an ambitious program aimed at interrupting the vector-borne transmission of *T. cruzi* called the Southern Cone Initiative (SCI).¹³⁵ Spraying of residual insecticides, improvement of housing, and education of at-risk populations are the core elements of the SCI. During the 25 years that the SCI has been in place, a striking level of success has been achieved. Ongoing population-based serologic surveillance in many areas has revealed major reductions in *T. cruzi* prevalence in younger age groups, as well as a gradual decrease in seropositivity rates among blood donors, clear evidence of the success of the program.^{124,130,171} Uruguay was certified free of vector-borne transmission in 1997, Chile followed 2 years later, and certification followed in Brazil in 2006. Major successes also have been achieved in Paraguay, Bolivia, and Argentina in the context of the SCI. In addition, programs similar to the SCI have been implemented in the Andean countries and in Central America, and major progress is being made in these regions as well.^{35,80} The broad successes of all these vector control programs in reducing transmission of *T. cruzi*, the expectation of their continued impact in the coming years, and the largely effective implementation of donor screening for Chagas disease mandated by statute in all 21 endemic countries constitute grounds for reasonable optimism regarding the ultimate elimination of *T. cruzi* transmission in the next decade or so as foreseen by the WHO.

The epidemiology of Chagas disease in Mexico is of special interest because historically it has been less well studied there than in the other endemic countries, and proportionally fewer public health resources have been dedicated to the problem. Moreover, the situation of Chagas disease in Mexico should be of particular interest because roughly 17 million Mexican immigrants currently live in the United States.¹⁹⁰ In the mid-1990s a national survey carried out in Mexico among blood donors showed an overall prevalence rate of *T. cruzi* infection of 1.5%. In 2006 Kirchhoff and coworkers¹⁰⁹ reported a confirmed prevalence of *T. cruzi* infection of 0.8% among donors in five blood banks in the states of Jalisco and Nayarit. Moreover, in that study four of nine recipients of *T. cruzi*-tainted blood products were found to be infected with the parasite, thus demonstrating clearly that transfusion transmission was taking place. These data, along with the results of other serologic surveys of donors, were carefully considered in the writing of the new national regulations for blood products that became law in 2012,¹⁴³ under which the screening of donated blood for Chagas disease is mandated nationally.¹⁷⁴

As far back as 1966, outbreaks in the endemic countries of *T. cruzi* transmission to groups of people through ingestion of food or drink presumably contaminated with infectious parasites from vectors have been reported.^{59,167,202,208} There is no doubt that reports of such outbreaks

have appeared more frequently in recent years. It is not clear, however, whether this increase results from an actual increase in *T. cruzi* transmission by this route or from a growing awareness of its possibility and an enhanced ability to investigate such outbreaks by public health authorities in the endemic countries. In either event, in terms of preventing such outbreaks it is important to recognize that they result not from a narrow *T. cruzi* problem but rather from the much broader problem related to a lack of adequate food safety standards that also results in the transmission of a variety of other pathogens.

Several dozen cases of *T. cruzi* transmission in laboratory settings were reported in the past, despite the negative publication bias relating to such incidents.⁸⁴ The fact that only one such report¹⁰⁶ has appeared during the last 15 years, however, suggests that accidental transmission may have been largely eliminated as increasingly stringent biosafety practices have been implemented in laboratories in which infective forms of *T. cruzi* are produced.

Despite the presence of the sylvatic cycle of *T. cruzi* in large areas of the southern and western United States, as noted earlier, only seven cases of vector-borne transmission to humans here have been described.⁶¹ In addition, in the 5 years following implementation of blood donor screening in the United States in 2007, during which time more than 40 million donors were screened, only 17 seropositive donors were identified who appeared to have chronic *T. cruzi* infection acquired from vectors in the United States.³² These data suggest that autochthonous transmission in the United States may be a bit more common than it had appeared to be. It is important to keep in mind, however, that these 17 donors with presumably autochthonously acquired chronic *T. cruzi* infection came to light through what is essentially a cross-sectional prevalence study that looked back over their entire lives. Thus their identification presents a limited perspective of the general incidence of vector-borne transmission and certainly says nothing regarding the secular trend of such transmission. In a review focused solely on Chagas disease and *T. cruzi* in Texas,⁷⁵ the results of earlier heterogeneous prevalence studies published over several decades were tabulated. Recognizing the obvious methodologic heterogeneity of the studies cited therein and the inherent risks of drawing inferences from such aggregated information, the data do suggest that in Texas at least autochthonous transmission of *T. cruzi* may be more common than previously thought. As in the case of the 17 infected blood donors, no inferences can be drawn from these data regarding a secular trend of such transmission, and overall it is still clear that vector-borne transmission is a rare event in Texas and other enzootic areas in the United States.^{136,137} Importantly, the last reported autochthonous case of acute *T. cruzi* infection acquired in the United States from vectors occurred in the early 2000s.⁶¹

Since the 1980s, roughly 15 laboratory-acquired and imported cases of acute *T. cruzi* infection have been reported to the Centers for Disease Control and Prevention (CDC), but only one imported case occurred in a tourist returning to the United States from a Chagas-endemic country.³⁶ Three instances of tourists returning to Europe from endemic regions with acute *T. cruzi* infection have been reported, however, as has a similar case in Canada.³⁹ It is clear from this paucity of imported cases of acute Chagas disease, especially when viewed against the backdrop of the many millions of tourists who visit the Chagas-endemic countries each year, that the risk of acquiring acute *T. cruzi* infection while visiting these areas is extremely low.

The number of people with chronic *T. cruzi* infections who live in the United States has grown considerably in recent decades. More than 23 million persons born in Chagas-endemic countries reside in the United States. Moreover, it merits mention that most of the 6 million non-Mexican immigrants from endemic countries who currently live here were born in regions where the prevalence of chronic Chagas disease is higher than it is in Mexico. The CDC estimated that 300,000 persons with chronic *T. cruzi* infection currently live in the United States, essentially all of whom were already infected when they emigrated from their home countries.¹⁶ Before donor screening began in 2007 a total of seven cases of transfusion transmission of *T. cruzi* had been reported in the United States and Canada,²¹⁰ and two additional instances were found in trace-back investigations done after screening was implemented.¹⁰⁵ The confirmed rate of *T. cruzi* infection in blood donors

since screening started in 2007 has been about one in 13,300, and more than 2000 serologically confirmed donors have been permanently deferred from further donation.⁵³ No cases of transfusion-associated transmission of *T. cruzi* are known to have occurred in the United States since donor screening began. Transplantation of organs obtained from three immigrants with chronic *T. cruzi* infections resulted in five cases of acute Chagas disease, one of which was fatal.³⁷ The last of these cases occurred in 2006, which may reflect the effect of organ donor screening programs that include serologic testing for *T. cruzi*.

Regarding the risk of congenital transmission of *T. cruzi* to infants born in the United States to chronically infected mothers, a reasonable estimate based on risk data from studies in Argentina and Brazil would put the number of such births per year at 63 to 315, but surprisingly only one such instance has been described.⁴⁰ Several issues likely underlie this enigma, but the low level of knowledge about Chagas disease among caregivers may result in substantial underreporting.²⁰¹

Hardly any information has been published that sheds light on the question of whether the rate of congenital transmission can be reduced by prophylactically treating women of childbearing age with either nifurtimox or benznidazole before they become pregnant. In the one investigation relevant to this question,⁶⁷ only a small number of women in the study group received treatment as adults. One would expect that parasitemias would have been reduced by the treatment, as was the case in the Benznidazole Evaluation for Interrupting Trypanosomiasis (BENEFIT) trial and other studies, and some of the treated women may have been cured parasitologically, but no data relevant to these questions were provided in the report. None of the infants born to any of the women in the study had congenital Chagas disease, thus suggesting that this prophylactic approach may be effective in reducing the rate of congenital transmission. A larger study needs to be done to address this issue adequately.

Pathology and Clinical Manifestations

Acute and Indeterminate Phases of Chagas Disease

The first sign of acute *T. cruzi* infection, which is seen much more commonly in children than in adults, can be a chagoma, which is an indurated and erythematous lesion at the site where the parasite entered host cells 10 to 14 days earlier.¹³ If the organisms entered through the conjunctivae, the patient may develop painless unilateral periorbital edema, which is called Romaña sign (Fig. 222.5). In either case, local histologic changes include infiltration of lymphocytes, interstitial edema, intracellular parasitism of myocytes and a variety of other cells, and reactive swelling of adjacent lymph nodes. Fever and malaise, in addition

FIG. 222.6 Intracellular *Trypanosoma cruzi* amastigotes in the cardiac muscle of a child with acute Chagas disease who died of acute myocarditis in Texas (H&E, $\times 900$). (From Kirchhoff LV. *Trypanosoma* species (American trypanosomiasis, Chagas' disease): biology of trypanosomes. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 8th ed. Philadelphia: Elsevier; 2015.)

to edema of the face and lower extremities, widespread lymphadenopathy, and hepatosplenomegaly, may develop as the parasites spread through the lymphatics and bloodstream from the site of initial multiplication. Occasionally patients with acute Chagas disease develop diffuse morbilliform rashes called *schizotrypanides*. Muscle cells can become heavily parasitized, and clinically manifest myocarditis develops in a small proportion of patients, occasionally precipitating fatal congestive heart failure^{144,149} (Fig. 222.6). On histologic examination of cardiac tissue from patients with acute myocarditis, patchy areas of parasitized cells are present, in addition to intense infiltration of mononuclear cells and necrosis. The pathognomonic *pseudocysts* also often seen in cardiac tissue are actually aggregates of *T. cruzi* amastigotes inside cardiomyocytes. Nonspecific electrocardiographic abnormalities may be present in tracings from patients with acute chagasic myocarditis, but the life-threatening dysrhythmias that can develop in patients with chronic cardiac Chagas disease usually do not occur.

Patients with acute Chagas disease can also have central nervous system (CNS) involvement, which was first described by Carlos Chagas.⁴¹ It is not known how often the parasites actually invade extravascular spaces of the CNS in acutely infected patients, but in general, neurologic findings are uncommon in patients with acute Chagas disease. In a particularly noteworthy study related to this issue, parasites were found in the cerebrospinal fluid of eight of 11 patients examined, but none had neurologic symptoms.⁸⁸ Nonetheless, meningoencephalitis does occur rarely in patients with acute Chagas disease, mostly in infants, and generally it is associated with a poor outcome.²⁰³ At a cellular level, focal presence of parasites accompanied by mononuclear cell infiltration has been described in all anatomic areas of the brain. Macrophages and glial cells can be heavily parasitized, but parasites are rarely seen in neurons. The clinical findings in patients with acute chagasic meningoencephalitis are indistinguishable from those found in acute CNS infections caused by other agents. Seizures can occur in variable patterns, and spasticity and hyperreflexia often develop.

In almost all patients with acute Chagas disease the signs and symptoms resolve spontaneously in 4 to 8 weeks, after which they enter the indeterminate phase of *T. cruzi* infection. This phase is characterized by a lack of symptoms, lifelong subpatent parasitemias, and detectable specific antibodies to *T. cruzi* antigens.

Congenital *T. cruzi* infection can be associated with premature rupture of membranes and preterm delivery, but there is no proven association with stillbirths and miscarriages. Most infants with congenital Chagas disease, which is a form of acute Chagas disease, are asymptomatic in the days after birth, and in the following months they evolve uneventfully into the indeterminate phase of *T. cruzi* infection. Infected neonates

FIG. 222.7 Chest radiograph of a Bolivian patient with chronic *Trypanosoma cruzi* infection, congestive heart failure, and rhythm disturbances. Pacemaker wires are present in the area of the left ventricle. (From Kirchhoff LV. *Trypanosoma* species (American trypanosomiasis, Chagas' disease): biology of trypanosomes. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 8th ed. Philadelphia: Elsevier; 2015.)

often display nonspecific signs and symptoms reminiscent of the TORCH syndrome.¹⁴² Meningoencephalitis, heart disease, and megaesophagus have occasionally been reported in congenitally infected infants.^{13,23,40,72,197}

Chronic Chagas Heart Disease

Fortunately, only 10% to 30% of persons with long-standing *T. cruzi* infections ever develop clinically manifest chronic Chagas disease. When associated signs and symptoms do develop, they typically first appear many years or even decades after initial infection. Nonetheless, rhythm disturbances and other cardiac abnormalities have been documented in chronically infected children.^{50,55} Cardiac problems are the most common clinical expressions of long-term *T. cruzi* infection, and since the 1990s, convincing experimental evidence has accumulated showing that the persistence of parasites in heart muscle stimulates chronic inflammation that leads to organ dysfunction and, in many cases, death.^{10,99,211} The inflammatory process can lead to a variety of cardiac rhythm disturbances, including atrial bradyarrhythmias and atrial fibrillation; premature ventricular contractions; bundle branch blocks, often of the right bundle; and complete atrioventricular block. These dysrhythmias can cause dizziness and syncope, and sudden death is common.^{86,160,195} Fibrosis, cardiomyopathy, and biventricular dilatation can develop as well, leading to congestive heart failure, thrombus formation, and strokes; strokes sometimes represent the first expression of the underlying disease, and they occasionally occur even in young persons (Fig. 222.7).

Chronic Gastrointestinal Chagas Disease (Megadisease)

The GI tract is the second most frequently affected organ system in patients with clinically manifest chronic Chagas disease, and it is estimated that 10% of persons with chronic Chagas disease eventually develop GI tract symptoms. The most common clinical manifestations of megadisease are caused by megaesophagus (Fig. 222.8), but problems related to megacolon (Fig. 222.9) are also common. Patients with megaesophagus have symptoms similar to those of idiopathic achalasia such as cough, odynophagia, dysphagia, regurgitation, and chest pain.^{58,164}

FIG. 222.8 Barium swallow radiographic study of a Brazilian patient with chronic *Trypanosoma cruzi* infection and megaesophagus. The markedly increased diameter of the esophagus as well as its failure to empty are typical findings in chagasic patients with megaesophagus. (Courtesy Dr. Franklin A. Neva, Bethesda, MD.)

FIG. 222.9 Air-contrast barium enema of a constipated Bolivian patient with megacolon and chronic Chagas disease. Markedly increased diameters of the ascending, transverse, and sigmoid segments of the colon are readily apparent. (From Kirchhoff LV. *Trypanosoma* species (American trypanosomiasis, Chagas' disease): biology of trypanosomes. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 8th ed. Philadelphia: Elsevier; 2015.)

Hypersalivation often accompanies all these symptoms, and substantial parotid gland hypertrophy has been observed in some untreated patients with megaesophagus. Aspiration can become a problem, and recurrent episodes of aspiration pneumonia are common in patients with untreated severe chagasic esophageal dysfunction. Malnutrition can combine with pneumonia to cause death in patients with megaesophagus, although this is not common today because of the availability of effective symptomatic treatment. The typical symptoms of patients with megacolon are chronic constipation and abdominal pain. Patients with severe megacolon can go for weeks without a bowel movement, and acute obstruction, sometimes associated with volvulus, can result in perforation,

septicemia, and death, but this scenario also is uncommon because of the widespread availability of surgical treatment.^{93,115} Children and adolescents who are chronically infected with *T. cruzi* have been known to develop cardiac dysfunction and/or megadisease, but the incidence is very low.

Trypanosoma cruzi Infection, Immunosuppression, and Transplantation

In patients with chronic Chagas disease immunosuppression can result in reactivation of the indolent *T. cruzi* infection in a manner and with a severity not seen in immunocompetent persons.^{12,19,96,153} In general, reactivation occurs in a small proportion of immunosuppressed persons who harbor the parasite chronically, but the precise incidence is not known. Immunosuppression is the only clinical context in which encephalitis and brain abscesses occur in persons with chronic *T. cruzi* infection. Reactivation after kidney and liver transplantation has been described, and in rare cases, abscesses in the CNS were involved.^{49,76,119,166,169} Reactivation of *T. cruzi* infections and associated CNS encephalitis or brain abscesses also have been reported in patients who become immunosuppressed in association with other illnesses. One patient was described in whom a tumor-like CNS lesion caused by *T. cruzi* was found at the same time chronic lymphocytic leukemia was diagnosed.¹⁷² Much more common, however, is the occurrence of *T. cruzi* reactivation in persons co-infected with *T. cruzi* and human immunodeficiency virus (HIV); dozens of such patients have been described, for the most part before HIV protease inhibitors became available.^{28,51,56,83,175} A large percentage of these patients had CNS mass lesions caused by *T. cruzi*, lesions that, as noted, simply do not occur in immunocompetent persons chronically infected with the parasite. Myocarditis also has been observed commonly in dually infected persons in whom *T. cruzi* has reactivated.¹⁷⁶ It is noteworthy that reactivation of chronic *T. cruzi* infection overall occurs only in a small minority of patients who also harbor HIV.

A panel of experts reviewed the limited available data relating to the transplantation of organs obtained from *T. cruzi*-infected donors.⁴⁸ These experts and others¹³² concluded that with informed consent, transplantation of kidneys and livers from infected donors is reasonable, but they emphasized that careful postoperative and long-term monitoring for *T. cruzi* infection in the recipients should be carried out, perhaps with guidance from staff at the CDC. Hearts from *T. cruzi*-infected donors should not be transplanted.¹¹⁴ Seropositive transplant recipients should be monitored similarly for acute or reactivation infection. Unfortunately, no information is available on which to base guidance for prophylactic trypanocidal treatment of patients in either of these situations.

Diagnosis

There are no specific epidemiologic or clinical markers for Chagas disease, and thus the diagnosis must be made by laboratory studies. In acute Chagas disease, the diagnosis is parasitologic, and the highly motile parasites often can be seen on microscopic examination of wet smears of anticoagulated blood or buffy coat. Parasites also can sometimes be seen microscopically in the pellets of spun cerebrospinal fluid (CSF),⁴⁸ but a brain biopsy is unlikely to be diagnostic if a careful search in blood and other fluids is negative. Moreover, determining whether a parasitologically positive patient has CNS involvement is not critically important because its presence does not alter the recommended treatment regimen, as is the case in HAT. PCR assays are sensitive and specific in acute Chagas disease, but they are not used widely because of their limited availability and technical complexity.^{110,178} Hemoculture and xenodiagnosis should not be attempted because they are prohibitively cumbersome, require several weeks to complete, and have sensitivities of only 50% to 70% even in the best of hands. Assays for *T. cruzi*-specific immunoglobulin M (IgM) lack accuracy and should not be used for diagnosing acute Chagas disease.

The approach to diagnosing congenital Chagas disease in infants merits special attention. As indicated schematically in (Fig. 222.10), all pregnant women with geographic or maternal risk should be tested serologically for *T. cruzi*. Among at-risk women in the nonendemic countries, the prevalence of chronic *T. cruzi* infection may vary considerably, depending on the countries from which the women have emigrated.

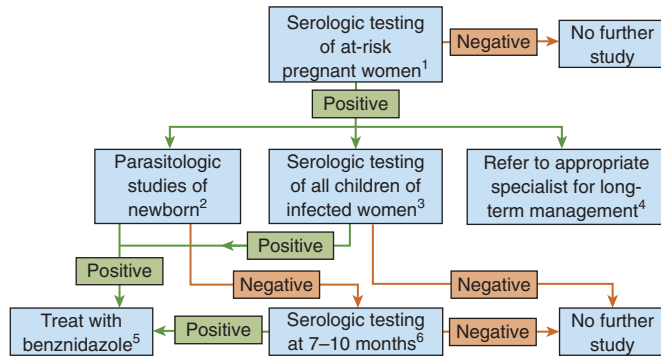

FIG. 222.10 Diagnosis and management of congenital Chagas disease.¹Mexico as well as all the nations of Central and South America are endemic for Chagas disease. Chagas disease is not endemic in any of the Caribbean Islands. Women born in Chagas disease-endemic countries, or who have resided therein for substantial periods of time, are at geographic risk for having Chagas disease. In addition, women who are not themselves at geographic risk, but whose mothers have such risk and are not known to be seronegative, are in turn considered to be at risk for Chagas disease.²The two approaches useful in this regard are microscopic examination of anticoagulated blood and polymerase chain reaction (PCR). Serologic testing of newborns is not useful because assays for specific immunoglobulin (IgG) will be positive, reflecting the mothers' chronic infection, and because IgM assays lack acceptable levels of sensitivity and specificity.³All children born to at-risk women should be tested serologically because several studies indicate that the rate of congenital Chagas disease in babies born to infected mothers is 2% to 10%.⁴The latter should include periodic monitoring for signs and symptoms of chronic cardiac and gastrointestinal Chagas disease followed by appropriate interventions when indicated. The usefulness or specific drug treatment in adults with chronic *Trypanosoma cruzi* infections has not been clearly demonstrated and is a matter of ongoing debate.⁵The parasitologic cure rate in babies with congenital Chagas disease approaches 100% when a full course of treatment is given during the first year of life.⁶The sensitivities of microscopic examination of anticoagulated blood and PCR are less than 100%. Thus an occasional baby who tests negative in these approaches right after birth may actually be infected with *T. cruzi*. Serologic testing for specific IgG should be delayed until maternal IgG has disappeared.

For example, in a study done among Hispanic immigrant women in Barcelona, Spain, where there is a substantial population of Bolivians, the seroprevalence rate was 3.5%,¹⁴⁸ whereas the rate among Hispanic immigrant women in Houston, Texas, who were mainly from Mexico and Central America, was only 0.25%.⁶³

No drugs or other measures are available for reducing the rate of congenital transmission. Thus having made the diagnosis of chronic *T. cruzi* infection in a pregnant woman, efforts then need to be focused on looking for evidence of congenital infection in the infant right after birth. Guidance on this process can be obtained at parasites@cdc.gov and by speaking with CDC staff at 404-718-4745. The general approach is to examine wet mounts and buffy coat of cord or whole blood obtained from the infant right after birth, and if parasites are not seen, to test the samples by PCR assay. The results of one study indicate that PCR assay on cord blood is more sensitive than microscopic examination.¹⁷ If results of these parasitologic approaches are negative, blood obtained from the infant 7 to 10 months after birth should be tested serologically. If all these assay results are negative, no further testing for congenital Chagas disease is warranted. If any of the assays gives a positive result that is confirmed on repeat testing, the infant is deemed to have congenital Chagas disease and should be treated with benznidazole as outlined later. Such treatment will result in parasitologic cure in nearly 100% of the infants treated, thus presumably eliminating the risk of their developing chronic symptomatic Chagas disease years later. It will also break the chain of congenital transmission in that the treated female infants will not pass the infection on to their infants years later, unless of course they become reinfected in the interim through vector-borne

transmission. An additional issue of importance is that other children of a pregnant woman found to be infected with *T. cruzi* should be tested serologically and, if positive, treated with benznidazole as indicated later.

With rare exceptions chronic Chagas disease is diagnosed by detecting IgG antibodies that bind specifically to *T. cruzi* antigens. It appears that detectable levels of such antibodies are universally present in persons chronically infected with *T. cruzi*. There is no credible evidence from properly structured studies that supports the concept of "seronegative Chagas disease." At present, at least a couple dozen serologic assays for chronic Chagas disease are available commercially,^{43,62,78,147,173} and they are used widely for screening donated blood and clinical diagnosis in the endemic countries, as well as in other areas to which persons with geographic risk have emigrated. As with all assays, the sensitivities and specificities are less than 100%, and false-positive results can occur with specimens from patients with leishmaniasis, syphilis, malaria, and other infectious and autoimmune diseases. Although historically serodiagnostic tests for Chagas disease have been plagued with false-positive and false-negative results, the validated tests commercially available today in general are at a par with tests for other infectious diseases. The WHO recommends that samples be tested in two assays based on different methodologies before diagnostic decisions are made.²⁰⁷ In Brazil the use of a single assay for both screening and diagnostic testing has been recommended officially. In the United States serologic testing is usually done in a single screening assay, followed by supplemental or confirmatory testing. Unvalidated in-house serodiagnostic tests for *T. cruzi* infection should not be used in any clinical or research context.

In the United States two assays are approved by the US Food and Drug Administration (FDA) for clinical testing (Chagatest Recombinante, Laboratorios Wiener, Rosario, Argentina; Chagas Kit, Hemagen Diagnostics, Inc., Columbia, MD). The Abbott Architect Chagas assay (Abbott Laboratories, Inc., Abbott Park, IL),^{1,156} which is an accurate chemiluminescence assay based on a mixture of four chimeric recombinant *T. cruzi* proteins, is not approved in the United States. It is approved and used widely for both donor and clinical testing in a majority of the Chagas-endemic countries. The Abbott Prism Chagas assay,⁴³ a high-throughput automated chemiluminescence assay based on the four recombinant proteins employed in the Architect Chagas, and the Ortho *T. cruzi* ELISA Test System (Ortho-Clinical Diagnostics, Raritan, NJ), an enzyme-linked immunosorbent assay (ELISA) based on a lysate of parasites grown in culture,⁷⁸ are the only assays approved by FDA for donor testing and are currently used to screen the US blood supply. A radioimmuno precipitation assay (Chagas RIPA),^{108,147} which is approved under the Clinical Laboratories Improvement Act (CLIA) for testing clinical and research samples, is available in my laboratory. This assay is also approved by FDA for confirmatory testing of donor samples that are positive in the Abbott Prism Chagas assay or the Ortho *T. cruzi* ELISA Test System. Finally, the Abbott ESA Chagas (Enzyme Strip Assay), also based on the group of recombinant antigens used in the Architect Chagas assay, is FDA approved for confirmatory testing of screen-positive donor samples.⁴⁷ Unfortunately, PCR assays do not have consistently high levels of sensitivity that would allow their use for confirmatory testing of screen-positive donor samples.¹⁷⁸

Treatment

Nifurtimox (Lampit, Bayer 2502) and benznidazole (Rochagan, Roche 7-1051) are the only two drugs available for treating patients with *T. cruzi* infection. There are no data from properly structured trials that justify the use of other drugs, either alone or in combination with each other or with nifurtimox or benznidazole, for treating any form of *T. cruzi* infection.¹⁶² Both nifurtimox and benznidazole are unsatisfactory from several perspectives.¹¹ Nifurtimox has been used to treat *T. cruzi* infection for more than 4 decades. It reduces the severity and duration of acute Chagas disease and decreases mortality. Substantial proportions of patients treated with nifurtimox experience bothersome side effects.⁹⁵ GI complaints include nausea, vomiting, abdominal pain, anorexia, and weight loss. Neurologic complaints related to nifurtimox can include restlessness, twitching, paresthesias, and insomnia. Fortunately, these symptoms usually disappear when the dosage is reduced or treatment is stopped.

The recommended daily dosage for nifurtimox is 15 to 20 mg/kg for children up to 10 years of age, 12.5 to 15 mg/kg for adolescents, and 8 to 10 mg/kg for adults. The drug should be given orally in four divided doses, and treatment should be continued for 90 to 120 days.

Benznidazole is viewed as the drug of choice by most specialists in the endemic countries.¹²⁶ Side effects include rash, granulocytopenia, and peripheral neuropathy.^{3,154} Overall it is fair to say that benznidazole is better tolerated by patients than nifurtimox, likely because of its lower incidence of bothersome GI side effects.

The recommended daily dosage for benznidazole is 5 to 10 mg/kg for children and 5 mg/kg for adults, in two or three divided doses, for 60 days. Thus the dosages of both nifurtimox and benznidazole vary as a function of the patient's age and weight, but generally not as a function of infection history, the levels of parasitemia, the presence of CNS disease, or other clinical manifestations. In the United States both nifurtimox and benznidazole are available only from the CDC Drug Service (404-639-3670), and specific guidance for the use of these drugs can be obtained from staff there as well.

The question of which groups of *T. cruzi*-infected persons should be given specific therapy has been the focus of intense discussion for decades. This is a thorny issue because benznidazole generally is effective in infants and children in all stages of *T. cruzi* infection, but it has limited efficacy in adults with long-standing chronic infection.⁶⁸ In general the efficacies of benznidazole and nifurtimox are similar. The consensus of experts in the endemic countries is that all persons with acute *T. cruzi* infection, including infants with congenital Chagas disease and patients with reactivated chronic infections caused by natural or iatrogenic immunosuppression, should be treated with either nifurtimox or benznidazole. An estimated 70% of immunocompetent acute patients will be cured parasitologically. Importantly, moreover, considerable data from benznidazole trials in congenitally infected infants in Argentina and Brazil indicate that the cure rate approaches 100% if treatment is given in the first year of life.^{2,145,177} Moreover, in most immunosuppressed patients the often life-threatening reactivations will be suppressed, although the likelihood of parasitologic cure is quite low and the risk of later reactivations will persist if immunosuppression continues.

In terms of how to treat persons who harbor *T. cruzi* chronically, the current evidence-based consensus is that chronically infected children and adolescents up to 18 years of age should receive specific treatment. Clinical trial data indicate clearly that a large proportion of patients in this group will be cured parasitologically.^{14,177,188}

In contrast, in adults with long-standing *T. cruzi* infection, including persons in the indeterminate phase as well as those with manifest chagasic symptoms, most of whom presumably were infected while quite young, the probability of parasitologic cure with either drug is less than 10%.^{27,116,204} Determining which treated patients are cured is challenging, moreover, because treatment suppresses parasitemias, as reflected in reduced rates of positivity in post-treatment PCR assays, and levels of anti-*T. cruzi* antibodies can remain positive for years.^{4,157} Until more recently, moreover, data from properly structured randomized clinical trials that assessed the effect of specific treatment in chronically infected adults have been lacking. A segment of this void was filled by the results of the BENEFIT trial.^{128,138} In this blinded, placebo-controlled trial of benznidazole versus placebo that was performed in Colombia, Argentina, and Brazil, 2854 *T. cruzi*-infected patients with mild cardiac disease were followed for a mean of 5.4 years. Unfortunately, although as expected parasite detection by PCR assay was reduced, benznidazole did not significantly reduce cardiac clinical deterioration or death. In view of these results, specific treatment of adults with long-standing *T. cruzi* infection and demonstrable cardiac disease cannot be recommended. Moreover, as noted, no adults in the indeterminate phase of chronic *T. cruzi* infection were included in the BENEFIT trial, and thus randomized clinical trial data that shed light on the potential usefulness of treatment of persons in this group are still lacking.¹²⁷ A panel of experts convened by the CDC in 2006,¹⁴ as well as the Ministries of Health in Brazil¹⁵² and Argentina,⁷⁹ recommended that treatment should be offered to adults with indeterminate phase disease and that, after discussion of the risks and possible benefits, a decision should be made by the treating physician and each patient.

Chronic Symptomatic Chagas Disease

The consensus among experts is that persons who have already developed cardiac or GI symptoms should not be given antiparasitic treatment. These patients should be referred to appropriate subspecialists, preferably persons with some familiarity with Chagas disease, for long-term monitoring and supportive treatment when appropriate.

The management of patients with chronic chagasic heart disease is supportive. Persons with chronic *T. cruzi* infection should have electrocardiograms done every 6 months or so because pacemakers have been shown to be useful in the management of dysrhythmias that develop in many patients in this group. The cardiomyopathy and consequent congestive heart failure of Chagas disease is generally managed with measures used in patients with cardiomyopathies from other causes.^{160,161} The usefulness of implantable cardioverter-defibrillators in patients with advanced chagasic heart disease is controversial and is the focus of a large, ongoing trial in Brazil.^{8,158}

Cardiac transplantation is an option in patients with end-stage Chagas heart disease, and hundreds of patients have had this procedure in Brazil, Argentina, and the United States.^{6,60,69,107} As might be expected, *T. cruzi* has been found in endomyocardial biopsies of transplant recipients, thus raising the possibility of early destruction of the new hearts by invasion of parasites. Nonetheless, long-term survival is greater in patients with Chagas disease who have undergone heart transplantation than in patients who have had heart transplants for diseases caused by other processes. It also merits mention that chagasic patients who have undergone cardiac transplantation may develop skin lesions containing high numbers of intracellular parasites. Conversely, encephalitis or cerebral abscess resulting from *T. cruzi* reactivation is rare after heart transplantation,¹⁹ even though this occurs commonly in HIV-infected patients with chronic *T. cruzi* infection in whom reactivation occurs.

Chagasic megaesophagus generally should be treated in the same way as idiopathic achalasia.^{82,159,164} Balloon dilation of the lower esophageal sphincter is the first approach to relieving symptoms, and patients in whom this approach fails generally are treated with laparoscopic surgical myotomy with a partial fundoplication. In patients with advanced megaesophagus esophagectomy with gastroplasty is often performed.¹⁵⁵

Chronically infected patients in the early stages of colonic dysfunction are generally managed with a high-fiber diet and occasional laxatives and enemas. Fecal impaction requiring manual disimpaction can occur, as can toxic megacolon and volvulus, both of which require surgery. Several surgical procedures have been used to treat advanced megacolon resulting from Chagas disease, and all involve removal of part of the rectum and resection of the sigmoid colon.⁷⁴

Prevention and Control

No vaccine or prophylactic drug is available for preventing transmission of *T. cruzi*.

The following measures are key elements in continuing the enormous progress that has been made to date in controlling Chagas disease:

- Control vector-borne transmission of *T. cruzi* by development of public health infrastructure capable of identifying areas where transmission occurs and implementing programs focused on the three core elements of the SCI: (1) housing improvement, (2) spraying of residual insecticides, and (3) education of populations at risk for acquiring *T. cruzi* infection.
- Serologically screen blood donors for chronic *T. cruzi* infection, and permanently defer seropositive donors.
- Serologically screen organ donors and transplant recipients for chronic *T. cruzi* infection.
- Serologically screen all pregnant women who have geographic or maternal risk for *T. cruzi* infection. Test all infants born to seropositive mothers parasitologically and, if need be, serologically, and treat infants with congenital Chagas disease with benznidazole.
- Educate tourists planning to travel to Chagas-endemic countries regarding the risk of *T. cruzi* transmission. Urge them to avoid sleeping in dilapidated dwellings and outdoors, but if they must, to take measures for reducing contact with vectors, such as screens and insect repellents.^{113,122} Special precautions beyond the usual measures

for reducing the insect exposure of campers, hunters, and others engaging in outdoor activities in the United States are not warranted.

- Serologically screen all children and adolescents through age 18 years who have geographic or maternal risk for *T. cruzi* infection.²⁰⁵ Treat seropositive persons so identified, and in the majority who will be cured parasitologically, the risk of their developing clinically manifest Chagas disease later in life and the risk of congenital transmission to their children presumably will be eliminated.
- Serologically screen all adults who have geographic or maternal risk for *T. cruzi* infection. Refer all seropositive persons to appropriate subspecialists, who ideally will have some knowledge of Chagas disease, for appropriate long-term monitoring and symptomatic treatment when necessary.
- Given the rarity of transmission of *T. cruzi* by ingestion of contaminated food or drink, reducing its risk in endemic areas cannot be productively approached with a sole focus on the parasite and its vectors. Rather, a reduction in its incidence can be achieved only through broad improvement in food safety standards and education.
- *T. cruzi* is classified as a risk group 2 agent in the United States, and a risk group 3 agent in some European countries. To avoid accidental transmission, laboratory staff who work with *T. cruzi* in culture or in infected vectors and mammals should strictly apply containment levels consistent with the risk group classification in their areas.^{20,91}

AFRICAN TRYPANOSOMIASIS (SLEEPING SICKNESS)

Biology, Life Cycle, and Mechanisms of Transmission of African Trypanosomes

HAT, also known as sleeping sickness, results from infection with flagellated protozoan parasites that are transmitted to humans by tsetse flies. The infecting trypanosomes first cause a febrile illness that in untreated patients is followed months or years later by progressive neurologic impairment and death. *T. brucei gambiense* and *T. b. rhodesiense*, two subspecies of the *T. brucei* complex, cause the West African (*gambiense*) and East African (*rhodesiense*) forms of sleeping sickness, respectively. These subspecies are morphologically identical, but nonetheless cause illnesses that are clinically and epidemiologically distinct (Table 222.1). These trypanosomes are transmitted by blood-sucking tsetse flies that belong to the genus *Glossina*.²⁰⁶ They become infected when they suck blood from infected mammalian hosts that have parasites

circulating in their bloodstream (Fig. 222.11). In the midgut of the vectors the parasites go through many cycles of multiplication and ultimately migrate to the salivary glands. Transmission occurs when parasites are inoculated into a mammalian host during a subsequent blood meal. The trypanosomes so injected then multiply in the blood and other extracellular spaces (Fig. 222.12). In contrast to *T. cruzi*, African trypanosomes do not have an intracellular phase in their mammalian hosts. They evade immune destruction indefinitely in a given mammalian host through a process called antigenic variation, which involves sequential gene switching that results in periodic changing of the antigenic structure of the parasites' predominant glycoprotein surface coat.^{45,89}

Essentially all transmission of African trypanosomes to both wild and domestic animals, and to humans, occurs in the cyclic fashion outlined earlier. It has not been shown that these trypanosomes can be transmitted by vectors other than tsetse flies, and similarly, mechanical transmission is not thought to be important. Transmission by blood transfusion is possible but appears to be extremely rare. The rate of congenital transmission is unknown, but such transmission also is thought to occur rarely.^{57,123,131,198} A few incidents of laboratory transmission of the parasites have been reported, but none since the 1990s.^{84,163}

Epidemiology

The endemic range of sleeping sickness is limited to sub-Saharan Africa.⁷⁰ It was much more of a problem in the past than at present, with major epidemics involving hundreds of thousands of persons described in the late 19th and the early 20th century.^{85,100,104,185} The problem was nearly eliminated by the mid-1960s, but after the end of the colonial era, as control programs fell by the wayside, there was a gradual resurgence in the number of new cases in several countries that peaked in the 1990s, primarily in Angola, Sudan, Uganda, the Democratic Republic of the Congo, and the Central African Republic. In response, control activities organized by national health authorities, nongovernmental organizations, and the WHO were intensified, and by 2009 fewer than 10,000 cases were reported annually to the WHO. By 2014 that number had come down to 3796, which was the lowest level since surveillance throughout the endemic range had started 75 years earlier. All told, 85% of these cases occurred in the Democratic Republic of the Congo. It is recognized that underreporting is a persistent reality, however, and it is estimated that the actual total number of cases in 2014 was around 20,000. Notwithstanding the latter figure, there is no doubt that barring major political and economic upheavals, sleeping sickness is headed for the history books. Consistent with this view, based on successes of the control programs, in 2009 a panel of experts summoned by the WHO developed a vision for the eradication of sleeping sickness, and in 2012 the WHO Neglected Tropical Diseases Roadmap targeted the elimination of sleeping sickness as a public health problem by 2020.^{71,103,118,181,183,192,200}

Human infection with *T. b. gambiense* occurs in widely distributed endemic foci in tropical rain forests of West and Central Africa. *Gambiense* trypanosomiasis is primarily a problem in rural populations, and tourists rarely become infected. Importantly 98% of reported cases of sleeping sickness are caused by *T. b. gambiense* infection, and humans are the only important reservoirs of this subspecies. These two facts are important elements that will facilitate the eventual elimination of sleeping sickness. In contrast, trypanotolerant antelope species in woodland areas and savannas of East and Central Africa are the principal reservoirs of *T. b. rhodesiense*. Importantly, cattle can also be infected with this and other trypanosome species, and they generally succumb to the infection.^{5,209} Because the risk for acquiring *T. b. rhodesiense* mostly results from contact with tsetse flies that primarily feed on wild animals, humans acquire *T. b. rhodesiense* infection only incidentally, usually while working in or visiting areas where the cycle of transmission involving vectors and natural reservoirs is present. About one or two imported cases of sleeping sickness are reported to the CDC each year, and almost all of them are in persons who acquired the infection in East African game parks.^{98,186} Patients with imported sleeping sickness occasionally are diagnosed in Europe and other nonendemic areas as well.^{54,133,184,194}

TABLE 222.1 Comparison of West African and East African Trypanosomiases

	West African (<i>Gambiense</i>)	East African (<i>Rhodesiense</i>)
Organism	<i>Trypanosoma brucei gambiense</i>	<i>Trypanosoma brucei rhodesiense</i>
Vectors	Tsetse flies (<i>palpalis</i> group)	Tsetse flies (<i>morsitans</i> group)
Primary reservoir	Humans	Antelope and cattle
Human illness	Chronic (late CNS disease)	Acute (early CNS disease)
Duration of illness	Months to years	<9 months
Lymphadenopathy	Prominent	Minimal
Parasitemia	Low	High
Epidemiology	Rural populations	Tourists in game parks; workers in wild areas; rural populations

FIG. 222.11 Life cycle of *Trypanosoma brucei* in its insect vectors and mammalian hosts. (From Centers for Disease Control and Prevention, Atlanta, GA.)

FIG. 222.12 *Trypanosoma brucei rhodesiense* parasites in rat blood. The slender parasite (arrow) is thought to be the form that multiplies in mammalian hosts, whereas the stumpy forms are nondividing and are capable of infecting insect vectors (Giemsa, $\times 1200$). (From Kirchhoff LV. *Trypanosoma* species (American trypanosomiasis, Chagas' disease): biology of trypanosomes. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 8th ed. Philadelphia: Elsevier; 2015.)

Pathology and Clinical Manifestations

A painful inflammatory lesion (trypanosomal chancre) may appear a week or so after inoculation of the parasites through the bite of an infected tsetse fly. Systemic sleeping sickness without invasion of the CNS is referred to as stage 1 disease. In this stage, the parasites multiply as they disseminate through the lymphatics and bloodstream, and a systemic febrile illness develops. Typically, bouts of high temperatures

lasting days are separated by periods without fever. There can be splenomegaly and widespread lymphadenopathy that can be prominent in stage 1 *T. b. gambiense* disease. The lymph nodes are often movable, discrete, and nontender. Cervical nodes are often readily apparent, and lymph node enlargement in the posterior cervical triangle, or Winterbottom sign, is a classic finding in *T. b. gambiense* disease. Maculopapular rashes and pruritus are common. Variable findings include headache, malaise, arthralgias, edema, weight loss, and tachycardia. These findings can develop in children as well as in adults.

Hematologic findings in stage 1 disease often include leukocytosis, anemia, and thrombocytopenia. In addition, high levels of immunoglobulins, consisting mainly of polyclonal IgM, as well as heterophile antibodies, anti-DNA antibodies, and rheumatoid factor, often are present. Inflammatory cytokines appear to have important roles in the pathogenesis of HAT.¹⁰¹ Antigen-antibody complexes may play a role in vascular damage and increased permeability that facilitate dissemination of the parasites. Endarteritis, with perivascular infiltration of both lymphocytes and parasites, may develop in lymph nodes and the spleen. Myocarditis often develops in patients with stage 1 disease and is much more common in *T. b. rhodesiense* infections than in *T. b. gambiense* infections.

Stage 2 sleeping sickness is defined as invasion of the CNS by trypanosomes that is accompanied by the insidious appearance of a wide variety of signs and symptoms. With time a picture of progressive daytime somnolence and indifference can develop (hence the name "sleeping sickness"), sometimes alternating with insomnia and restlessness at night.^{45,102} Speech may become halting and indistinct, and a listless gaze accompanies a loss of spontaneity. Extraparasympathetic signs may include fasciculations, choreiform movements, and tremors. Ataxia is common,

and the patients may appear to have Parkinson disease, with tremors, hypertonia, and a shuffling gait. In untreated patients, progressive neurologic impairment ends in coma and death.

The presence of parasites in perivascular areas in the CNS is accompanied by intense infiltration of mononuclear cells. Abnormalities in CSF can include increased intracranial pressure, increased total protein concentration, and pleocytosis. In addition, trypanosomes are frequently found in CSF in patients with stage 2 disease.

The most notable difference between the East African and West African forms of sleeping sickness is that the latter generally follows a more acute course. Typically, tourists with *rhodesiense* disease develop systemic signs of infection before returning home or shortly thereafter. As the illness progresses persistent tachycardia unrelated to fever is common in *T. b. rhodesiense* trypanosomiasis, and death may result from congestive heart failure and arrhythmias before stage 2 disease develops. In general, the historical record indicates that untreated *T. b. rhodesiense* trypanosomiasis can lead to death in a matter of weeks to months, sometimes without a clear distinction between the hemolymphatic and CNS stages. In contrast, *T. b. gambiense* infection persists subclinically for many months or even years before life-threatening neurologic manifestations develop. A comparison of the epidemiologic and clinical features of East and West African trypanosomiasis is presented in Table 222.1.

Infants and Children

HAT may manifest in any age group. Abortion or perinatal death of infected babies may occur but not be reported as HAT. As noted, congenital transmission does occur but appears to be quite rare. Nonetheless, recommendations regarding the screening of pregnant women and the infants born to infected mothers in endemic areas have been published. In community screening programs women found to have HAT who are of childbearing age should undergo pregnancy testing. The newborns of mothers with HAT should be evaluated by parasitologic methods including examination of cord or other blood as early as possible. The card agglutination test for trypanosomes (CATT) should not be used in infants. If the result of initial testing in at-risk infants is negative, the test should be repeated in 6 months. In addition, because cases often occur in family clusters, all children in a family unit in which an infected adult has been identified should be evaluated for HAT even if they are asymptomatic. Overall, the incidence in young children appears to be lower than in adults.

Children with HAT may be asymptomatic or may present with nonspecific signs and symptoms that in general are similar to those observed initially in adults.^{31,66,112} Lymphadenopathy is less frequently reported in children younger than 7 years compared with adults.²⁵ In infected small children headache, sleeping disorders, or motor weakness may be difficult to evaluate, and such findings may be accompanied by neuropsychiatric manifestations. There appears to be a higher incidence of stage 2 disease in children younger than 2 years of age. The reason may be that nonspecific clinical manifestations are difficult to differentiate from other common co-endemic febrile illnesses of childhood in endemic areas, such as malaria. This delay in diagnosis and treatment can result in CNS damage.

Diagnosis

In contrast to Chagas disease, a definitive diagnosis of sleeping sickness always requires detection of parasites.²⁶ In a patient at risk for sleeping sickness, the search can begin with microscopic examination of Giemsa-stained smears or wet preparations of fluid expressed from a chancre or aspirated from a lymph node. If no parasites are seen by these approaches, similar study of serial blood samples should be the next step. If no trypanosomes are seen initially in blood samples, microscopic examination of centrifuged microhematocrit tubes containing acridine orange or a buffy coat wet preparation may be useful. In general, the likelihood of finding parasites in blood is higher in patients with *T. b. rhodesiense* disease than in persons infected with *T. b. gambiense* and is greater in stage 1 disease than in stage 2. Parasites can sometimes be seen in bone marrow aspirates. In addition, this material can be inoculated into liquid culture medium, and lymph node aspirates, CSF, blood, and buffy coat can be processed similarly.

CSF must be examined in all patients suspected of having sleeping sickness. In a patient in whom parasites have been found in other sites, any abnormality in CSF parameters must be viewed as pathognomic for stage 2 disease and prompt the use of a treatment regimen appropriate for that stage. Parasites also may be seen in the pellet of spun CSF. In at-risk patients with abnormal CSF parameters in whom trypanosomes have not been found, HIV-associated CNS infections such as cryptococcosis and tuberculous meningitis should be included in the differential diagnosis.

Several serologic tests, such as CATT, for *T. b. gambiense*, are commercially available.^{44,97,199} Their ease of use makes them valuable for epidemiologic surveys, but their variable sensitivity and specificity restrict their use to surveys, and decisions regarding the treatment of individual patients must be based on parasitologic diagnoses. New serologic assays are being developed.^{21,170} Sensitive and specific PCR assays for detecting African trypanosomes in humans have been developed and when available can be productively used to examine all the samples mentioned earlier,¹⁵⁰ and other molecular assays are in the pipeline.^{29,81,141} Unfortunately, however, in most endemic areas the lack of necessary technical and human resources stands in the way of the widespread use of these methods.

Treatment

The drugs used for treatment of HAT are pentamidine, suramin, eflornithine, melarsoprol, and nifurtimox (see Table 222.2). In the United States, these drugs can only be obtained from the CDC Drug Service (404-639-3670). Therapy for HAT must be individualized on the basis of the infecting subspecies, the stage of the infection, adverse reactions, and rarely drug resistance. Guidance for the use of these drugs for treating HAT is presented Table 222.2.

Pentamidine is the drug of choice for treating stage 1 *gambiense* HAT. The dose for adults as well as children is 4 mg/kg per day, given intramuscularly or intravenously for 7 to 10 days. Common, immediate adverse reactions include nausea, vomiting, hypotension, and tachycardia. These reactions are usually transient and do not warrant cessation of treatment. Other adverse reactions include nephrotoxicity, abnormal liver function tests, neutropenia, hypoglycemia, rashes, and sterile abscesses. Suramin is an alternative for stage 1 *T. b. gambiense* infection.

Suramin is highly effective against stage 1 *rhodesiense* HAT. It can cause serious adverse effects, however, and must be given under the close supervision of a physician. A 100- to 200-mg intravenous dose should be given initially to test for hypersensitivity. The dosage for adults is 20 mg/kg on days 1, 5, 12, 18, and 26. Suramin is given by slow intravenous infusion of a freshly prepared 10% aqueous solution. Roughly one patient in 20,000 has an immediate, severe, and potentially fatal reaction to the drug that can involve nausea, vomiting, shock, and seizures. Less severe reactions include photophobia, fever, arthralgias, pruritus, and skin eruptions. Nephrotoxicity is the most common important side effect of suramin, and transient proteinuria frequently appears during treatment. Urinalysis should be performed before each dose, and therapy should be discontinued if proteinuria increases or if

TABLE 222.2 Drugs Recommended for Treatment of the African Trypanosomiasis

Causative Agent	CLINICAL STAGE	
	1	2
<i>Trypanosoma brucei gambiense</i>	Pentamidine	Eflornithine
	Alternative: suramin	Alternatives: eflornithine/nifurtimox; melarsoprol
<i>Trypanosoma brucei rhodesiense</i>	Suramin	Melarsoprol

From Kirchhoff LV. Agents of African trypanosomiasis (sleeping sickness). In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 8th ed. Philadelphia: Elsevier; 2015.

red blood cells and casts appear in the sediment. Suramin should not be given to patients with any degree of renal insufficiency.

Eflornithine is highly effective for treating both stages of *gambiense* HAT. In the trials on which the FDA based its approval, eflornithine cured more than 90% of 600 patients with stage 2 *T. b. gambiense* disease. The recommended dosage schedule is 400 mg/kg per day, given intravenously in four divided doses, for 2 weeks. Adverse reactions include diarrhea, anemia, thrombocytopenia, seizures, and hearing loss. The high dosage and length of therapy required are serious disadvantages that make the widespread use of eflornithine a challenge. A randomized trial comparing the standard eflornithine regimen (400 mg/kg per day infused over 6 hours for 14 days) with nifurtimox-eflornithine combination therapy (oral nifurtimox, 15 mg/kg per day in three divided doses, plus intravenous eflornithine, 200 mg/kg per day in two divided doses, both for 7 days) in adults with stage 2 *gambiense* HAT showed greater efficacy and reduced side effects with combination therapy, thereby making this approach suitable for first-line use.

The arsenical melarsoprol is the drug of choice for the treatment of *T. b. rhodesiense* HAT with CNS involvement (stage 2 disease) and is an alternative agent for stage 2 *gambiense* disease.⁷ The “short course” of melarsoprol that is currently recommended has been shown to be noninferior to the decades-old course of therapy for *T. b. rhodesiense*, which was administered over several weeks and was much more toxic.^{22,46} The recommended short-course regimen involves melarsoprol in 10 daily doses of 2.2 mg/kg intravenously, each dose given with prednisolone (1 mg/kg).

Melarsoprol is very toxic and should be administered with close medical supervision. As noted, patients being treated with melarsoprol should also receive prednisolone to reduce the likelihood of drug-induced encephalopathy.^{24,151} Without prednisolone prophylaxis, the incidence of reactive encephalopathy in treated patients was as high as 18% in some studies. Signs of reactive encephalopathy include high fever, tremor, headache, seizures, impaired speech, and even coma and death. Treatment with melarsoprol should be stopped at the first sign of encephalopathy but can be resumed cautiously at lower doses a few days after signs have resolved. Extravasation of the drug results in serious local reactions. Abdominal pain, vomiting, nephrotoxicity, and myocardial damage can occur as well.

Prevention

Trypanosomiasis in Africa has long presented complex enzootic and public health challenges. As noted earlier, enormous progress has been made in endemic areas through programs that focus on vector control, combined with early diagnosis and treatment of infected persons. In more recent years, increasingly integrated programs run by the WHO, along with its governmental and nongovernmental partners, have served as a framework for advancing the control of tsetse fly populations and for reducing transmission to humans, and the number of reported cases has reached historic lows. Major elements underlying the optimism regarding the ultimate elimination of HAT are the facts that humans are the only important reservoirs for *T. b. gambiense* and that 98% of HAT cases currently reported are caused by *T. b. gambiense*. Importantly, moreover, although many challenges lie ahead, no major scientific discoveries are necessary for the elimination of HAT. In this context, there is no doubt that, barring major political and economic upheavals in the endemic countries, HAT is headed for the history books. The process of its elimination likely will be facilitated by the application of new technologies, such as the electronic geospatial database, HAT-Atlas,¹⁸² and progress additionally may be enhanced by the development of novel rapid individual diagnostic tests,³⁰ as well as simple oral treatment regimens.¹⁹⁶ Based on successes of the control programs, in 2009 a panel of experts convened by the WHO developed a vision for the elimination of sleeping sickness, and in 2012 the WHO Neglected Tropical Diseases Roadmap targeted the elimination of sleeping sickness as a public health problem by 2020.^{71,103,118,181,183,192,200}

Tourists can reduce their risk of becoming infected with African trypanosomes by avoiding areas known to be endemic or enzootic and by using insect repellent along with protective clothing. Neither chemoprophylaxis nor a vaccine is available to prevent transmission of the parasites.

Naegleria, *Acanthamoeba*, and *Balamuthia* Infections

223

Tina Q. Tan

Interest in free-living amebae has increased since demonstration of their pathogenicity and, more recently, their role as reservoirs and vectors for potentially pathogenic bacteria, such as *Legionella pneumophila*, *Vibrio* spp., *Listeria* spp., and *Mycobacterium avium*. Small free-living amebae of the genera *Naegleria*, *Acanthamoeba*, and *Balamuthia* cause severe central nervous system (CNS) infections in humans and animals that are characterized by few distinguishing symptoms and an almost uniformly poor prognosis. Although these severe infections are uncommon, for optimal treatment it is important to recognize and diagnose them early.^{153,158}

Although small free-living amebae share structural and pathogenic similarities, the infections they cause have distinctive epidemiology, clinical presentation and course, neuroimaging, immunology, and pathology. Primary amebic meningoencephalitis caused by *Naegleria fowleri* is an acute fulminant illness that affects healthy children and young adults and usually results in death within 1 week of presentation. Almost invariably, the patient has a recent history of swimming in bodies of warm fresh water, although there are recent reports of acquiring the infection through nasal irrigation using a neti pot sinus rinse. In contrast, granulomatous amebic encephalitis caused by *Acanthamoeba* spp. or *Balamuthia mandrillaris* (formerly leptomysid amebae) is an insidious, subacute, and protracted illness that affects primarily, but not exclusively, immunocompromised or debilitated patients and leads to death in weeks to months. Typically, the patient has no history of recent exposure to fresh water. One other species of ameba belonging to the genus *Sappinia* has also been identified as a cause of severe encephalitis.¹⁵⁴

Despite these differences, the prognosis of CNS infection caused by *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* is similarly dismal, with few reports of survival. In the handful of cases that survived from the hundreds reported, recognition, early diagnosis, and timely administration of appropriate antimicrobial treatment were crucial to achieving a successful outcome. *Acanthamoeba* spp. also are associated with disseminated cutaneous, pulmonary, or sinus infection in immunocompromised hosts and with chronic painful and potentially sight-threatening keratitis in association with use of contact lenses or corneal trauma in otherwise healthy patients.

The pathogenic potential of small free-living amebae was recognized first during polio vaccine trials in the 1950s, when they were found to cause cytotoxicity in contaminated cell cultures.^{29,64} Subsequently, the fulminant fatal encephalitis that followed intracerebral injection or intranasal instillation of tissue culture fluid in experimental mice and monkeys showed pathogenicity and a potential route for human infection.^{22,28,29} The first cases of human infection caused by small free-living amebae were recognized in four children from southern Australia by Fowler and Carter⁴⁶ in 1965 and soon afterward by Butt¹⁴ in Florida.

More recently, Visvesvara and colleagues^{157,159} isolated and named *B. mandrillaris*, a new agent of amebic meningoencephalitis, from the brain of a mandrill baboon. The first reported human case of *B. mandrillaris* encephalitis was in a patient with acquired immunodeficiency

syndrome (AIDS).³ Reports of infection in immunocompetent hosts have followed.^{7,36,48,70,117} Subsequently, infections caused by free-living amebae have been reported worldwide.^{4,72,86,87,97,120} Finally, the first case report of nonfatal CNS disease, in an otherwise healthy adult, caused by *Sappinia diploidea*, a free-living ameba normally found in soil contaminated with elk and buffalo dung, adds to the list of pathogenic small free-living amebae and suggests that others may be identified in the future.^{51,110,161}

EPIDEMIOLOGY

Pathogenic and opportunistic free-living amebae are found worldwide and are cosmopolitan in their distribution, living primarily in soil, but also in seawater, drinking water, swimming pools, sewage, eyewash solutions, contact lenses, dialysis units, dental treatment units, in dust, inside vertebrates, on plants, and in the air.^{38,102,116,135} They are spread readily by wind and water currents. In humans, infection with free-living amebae causes primary amebic meningoencephalitis, granulomatous amebic meningoencephalitis, disseminated granulomatous disease (cutaneous, pulmonary, kidney, or sinus), and keratitis.^{86,87,130}

Although they are rare, cases of infection caused by *N. fowleri* have been reported throughout the world.⁴⁵ As of 2015, well over 200 cases of primary amebic encephalitis have been documented worldwide, with approximately half occurring in the United States.^{25,130} In the United States between 1962 and 2008, 135 fatal cases of primary amebic meningoencephalitis were reported to the Centers for Disease Control and Prevention (CDC).^{101,169} Most of them occurred in the summer and in young children. Increased water temperatures, whether from thermal pollution or sunlight, provide the ideal environment for proliferation of *N. fowleri*.^{148,162} Cases typically are associated with a history of swimming, diving, or playing in bodies of warm fresh water, brackish habitats with a soil and water interface, artificial lakes, hot springs, and thermally polluted rivers and streams.^{25,32,45,90,101,148} Researchers have postulated that thermal pollution, particularly from overflow of power plants, or inadequate chlorination of water kills off normal thermosensitive and chlorine-sensitive fauna, shifting the balance in favor of thermotolerant, less chlorine-sensitive, pathogenic *N. fowleri*.¹³⁰ In North America, cases of primary amebic meningoencephalitis tend to be clustered in the warmer southern states and Mexico.¹³⁰ In one study, almost 50% of freshwater lakes in Florida contained *N. fowleri* when the temperature was 30°C or higher.¹⁶² *N. fowleri* may be found in colder areas, however. In temperate regions, distribution of *N. fowleri* is limited by seasons, being greatest during summer and early fall.¹⁴⁸ *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* were present year-round in lakes in the Tulsa region of Oklahoma.⁶⁷ Although it is most prevalent in areas where water temperatures are higher, *N. fowleri* has the ability to overwinter, in cyst form, in sediment at the bottom of lakes.¹⁶² Cases of fatal *N. fowleri* infection acquired in Minnesota have been reported.⁷³

Small outbreaks of primary amebic meningoencephalitis have been described. Over a 3-year period, from 1962 to 1965, 16 swimmers died

after being exposed to warm contaminated and inadequately chlorinated water in an indoor pool in Czechoslovakia.^{18,130} Similarly, eight cases of fulminant meningoencephalitis associated with exposure to the water of an artificial lake in Richmond, Virginia, were recognized retrospectively as being caused by *N. fowleri*.¹⁶ Finally, five cases of primary amebic meningoencephalitis caused by *N. fowleri* occurred in 1990 in people swimming in a drainage canal in Mexicali, Mexico.⁸⁰

Disease also has been documented in patients with no history of exposure to fresh water. Atypical exposures have included bathing in domestic bath water, playing in a warm muddy puddle, and being baptized by full-body immersion.^{4,9,89} *N. fowleri* also has been shown in domestic tap water.^{39,89} Although cases of infection have not followed ingestion of drinking water contaminated by amebae, fatal infection was associated with washing in tap water heated to high temperatures in pipes by the summer sun in South Australia and with exposure to contaminated domestic water in Arizona.^{2,39,89} Recently, the CDC reported the first case of fatal primary amebic meningoencephalitis, occurring in a 4-year-old child, associated with culturable *N. fowleri* in tap water from a treated public drinking water system. The only water exposure that this child had was the water in a lawn water slide on which they had played.²⁶

Infections occur far more frequently in previously healthy children and young adults than in other age groups, presumably because youngsters are most likely to remain in water for prolonged periods and to disturb sediment containing amebae by diving and swimming underwater.^{25,101} In one series of primary amebic meningoencephalitis cases, boys outnumbered girls 12 to 1, presumably because boys are more likely than girls to engage in aquatic horseplay.¹⁵⁶ The incubation period in natural human infection is 2 to 15 days after exposure.^{9,25,101} Death usually ensues within 1 week of presentation (generally within 72 hours).

Acanthamoeba spp. are among the most prevalent protozoa found in the environment, being found in soils from tropical to arctic regions. They are important components of the food chain and promote plant growth by predation on soil bacteria. *Acanthamoeba* spp. are prevalent in natural and artificial habitats that include fresh, brackish, sea, potable, or stagnant water; in sewage; in improperly treated swimming pools; and in taps, sinks, hot tubs, air-conditioning units, aquaria, flowerpots, showers, dialysis units, dental units, ventilators, and ventilation units in homes and hospitals.^{19,43,87,127,130} Although warm waters might enhance their numbers, pathogenic amebae may be isolated year-round from water samples in the United States.¹⁶² Their distribution and viability are governed primarily by availability of a bacterial food source; soil texture; water temperature, pH, and salinity and by ultraviolet light and desiccation.^{116,130} Growth of *Acanthamoeba* spp. is inhibited by temperatures of 35°C to 39°C. Although *Acanthamoeba* spp. seemingly are ubiquitous in water, *Acanthamoeba* infections generally are not associated with a history of recent swimming or water activities.¹³⁰ Acquisition occurs by inhalation or direct contact with contaminated soil or water.

In contrast to *N. fowleri*, *Acanthamoeba* spp. are opportunistic pathogens. Granulomatous amebic encephalitis and disseminated disease caused by *Acanthamoeba* spp. generally are seen in immunocompromised hosts or in patients with underlying disease or debilitation, such as that due to malignancy, cancer chemotherapy, corticosteroid treatment, organ transplantation, human immunodeficiency virus, diabetes, or malnutrition.^{86,87} *Acanthamoeba* spp. cause keratitis in otherwise healthy individuals by directly attacking the corneal surface, usually in association with poor contact lens care or corneal trauma. Although cases of CNS or disseminated *Acanthamoeba* infection are extremely rare, in 2015, the estimated prevalence of amebic keratitis worldwide was one to nine per 100,000.^{85,130} However, in recent years, the number of *Acanthamoeba* keratitis cases has been increasing in developing countries, correlating with the increased number of contact lens wearers.

Comparatively less is known about *B. mandrillaris*. It is closely related to *Acanthamoeba* and causes a similar spectrum of infections that includes granulomatous amebic encephalitis and cutaneous and sinus disease.¹³⁰ Although initial cases of *B. mandrillaris* infection were confined to immunocompromised and debilitated hosts, its ability to cause disease in apparently healthy children is well documented.^{7,36,49,70,117} By 2012,

more than 200 cases of human infection had been reported.^{12,84,130} *Balamuthia* inhabits soil and water; it has been isolated in soil from a flowerpot associated with a case of amebic encephalitis in a child from northern California.¹²³

As with *Acanthamoeba* spp., granulomatous encephalitis caused by *B. mandrillaris* seems to occur after inhalation of airborne cysts or soil contamination of breaks in the skin. The patient generally has no history of recent exposure to fresh water. To date, 50% of cases of *Balamuthia* infection reported in the United States have occurred in patients of Hispanic ethnicity.^{7,125} The majority of cases worldwide have also been reported in children and young men of Hispanic ethnicity. Although this statistic most likely is a result of environmental exposure, a genetic predisposition may exist. Among California cases of balamuthiasis, most cluster in the southern part of the state. Researchers have postulated that the area's dry, warm soil is conducive for the amebae and that large-scale agriculture in these areas increases the likelihood of workers being exposed to soil or wind-blown particles. Cases of *B. mandrillaris* infection linked directly to incidental exposure to soil or to blowing soil while traveling in an open car or by motorcycle are reported.^{36,70,123,127} Although *Balamuthia* encephalitis is a zoonosis, animals do not represent a source of infection for humans.

Despite their seeming ubiquity in the environment and ample opportunity for contact with humans compared with other parasitic protozoa, such as *Entamoeba*, malaria and trypanosome infections caused by free-living amebae are extremely rare. Given the enormous number of exposures to water containing *Naegleria*, why so few individuals become infected remains unknown. Only seven cases of primary amebic meningoencephalitis were reported in Florida during a 14-year period, despite estimates of billions of potential exposures in contaminated freshwater lakes during that time period.¹⁶² Epidemiologic investigations of cases typically find that many other individuals swam in the same water at the same time but did not become ill. Factors other than the presence of amebae, such as host susceptibility, anatomy, inoculum size, and activity at the time of exposure, have been implicated.¹⁶² Nonetheless, in recent years, an increase in the number of diagnoses of primary amebic meningoencephalitis cases has been noted.^{82,168} The increase probably reflects a combination of greater recognition of the pathogenic potential of free-living amebae, improved diagnostic techniques, and a growth in the numbers of immunocompromised hosts.

Acanthamoeba organisms can infect the cornea directly, after trauma, or, most commonly, in association with the combination of extended-wear soft contact lens use and subsequent exposure to contaminated water.^{132,143} Major risk factors for development of amebic keratitis include poor compliance with care of daily-wear soft contact lenses, particularly use of homemade saline solutions using nonsterile tap water that may be contaminated with amebae; use of chlorine release lens disinfection systems; and inadequate cleansing of lens cases, which encourages growth of a bacterial biofilm that acts as a nidus and a food source for amebae.^{113,142} Wearing contact lenses while swimming or in hot tubs, which potentially may be contaminated with amebae, is similarly risky.¹¹⁸

Since the first cases of amebic keratitis were described in the early 1970s, the incidence has increased dramatically. Between 1973 and 1984, slightly more than 200 cases of amebic keratitis were reported to the CDC. By 2002, in the United States, more than 3000 cases had been reported and 1 in 250,000 people were estimated to be affected.^{68,79,105,130} The increased incidence most likely is due to increased use of contact lenses, particularly of the soft, extended-wear variety. Although many of these lenses were marketed as products requiring "low care," many patients interpreted this designation as meaning "no care."¹¹³

ORGANISMS

In contrast to the related true parasite protozoa *Entamoeba* spp., *Naegleria*, *Acanthamoeba*, and *Balamuthia* spp. are amphizoid protozoa, capable of existing as free-living amebae and as parasitic pathogens.¹³⁰ *Naegleria* spp. are ameboid flagellates found primarily in moist soil and warm fresh water.⁹⁰ Although more than 27 separate *Naegleria* spp. have been identified, to date only *N. fowleri* is associated with human infections.^{32,130} *Naegleria* spp. can exist in three forms: an active feeding trophozoite, a rarely seen dormant cyst (Fig. 223.1), and a flagellate form (Fig. 223.2).⁹⁰

Of these forms, only the trophozoite is found in tissue or cerebrospinal fluid (CSF). The trophozoite of *N. fowleri* is smaller than that of *Acanthamoeba* spp., measuring 8 to 15 μm in diameter, with a conspicuous nucleus containing a large, dense central karyosome without peripheral chromatin lining the membrane.⁹⁴ *Naegleria* trophozoites move slowly by extension of broad, rounded anterior pseudopodia (lobopodia). This feature may be noted on a warm saline preparation or in CSF specimens. *Naegleria* cysts are spherical, measure 7 to 12 μm in diameter, and have a single-layered outer membrane.

FIG. 223.1 Trophozoites of *Naegleria*.

FIG. 223.2 Flagellate form of *Naegleria fowleri*.

Approximately 20 *Acanthamoeba* spp. are identified by morphologic criteria.¹³⁰ Because morphologic distinctions do not always correlate with results of molecular typing, however, classification is complex and is currently under review.⁸⁷ Molecular classification is ongoing. The life cycle of *Acanthamoeba* spp. consists of two stages: an actively feeding and dividing trophozoite and a dormant cyst stage (Fig. 223.3).¹⁰⁷ The trophozoite is 15 to 40 μm . The nucleus is vesicular; has a large, dense central “targetoid” nucleolus; and is surrounded by vacuolated cytoplasm. Locomotion typically is sluggish, by extrusion of multiple fine spiny pseudopodia (acanthopodia).⁹⁴ *Acanthamoeba* trophozoites feed on bacteria, yeasts, and algae. *Acanthamoeba* cysts are smaller, 15 to 20 μm , with a distinct, wrinkled, thick double wall. Encystation occurs in response to adverse environmental conditions, such as desiccation, scarcity of food, and changes in pH or temperature. *Acanthamoeba* cysts are particularly hardy; they are intrinsically resistant to chlorination and sterilization of potable water, to biocides used for disinfecting bronchoscopes and contact lenses, and to antibiotics; they may remain viable for decades after freezing.^{34,76,99} *Acanthamoeba* is the only pathogenic free-living species isolated from marine water. *Naegleria* spp. do not tolerate sea water.

Few *Acanthamoeba* spp. have been associated with human infections. Among the potentially pathogenic species, *Acanthamoeba culbertsoni*, *Acanthamoeba castellanii*, *Acanthamoeba astronyxis*, and *Acanthamoeba polyphaga* are prominent.⁹⁷ On the basis of 18S rRNA gene sequences, *Acanthamoeba* spp. are divided into 15 genotypes (T1 through T15). At present, no clear consensus has been reached regarding which genotypes are pathogenic. Genotypes T1, T4, T7, T10, and T12 are found among cases of granulomatous encephalitis, whereas isolates associated with keratitis fall into genotypes T3, T4, and T11.^{11,44,87,145} Genotype T4 makes up 94% and 80% of keratitis and nonkeratitis *Acanthamoeba* isolates, respectively,¹¹ presumably reflecting the preponderance of this genotype in the environment. Rare genotypes, such as T1, T10, and T12, are found only in CNS disease and are not found in the environment.

B. mandrillaris is the only pathogenic *Balamuthia* spp. identified to date.^{130,136} It exists as either an active trophozoite or a dormant cyst (Fig. 223.4). The cysts are highly resistant to physical and chemical conditions. Trophozoites are similar in appearance to *Acanthamoeba* spp. but larger (50 to 60 μm in diameter), and the spherical cyst stage (10 to 30 μm in diameter) has a triple-layered wall on electron microscopy consisting of an outer thin and irregular ectocyst, an inner thick endocyst, and a middle amorphous fibrillary mesocyst. *Balamuthia* trophozoites typically have a single vesicular nucleus, often with multiple large, dense nucleoli. Movement occurs by extension of broad pseudopodia. *Balamuthia* has been isolated more recently from environmental soil samples.⁴¹ Because of its slow growth, it may have been obscured in environmental cultures by overgrowth of more rapidly growing bacteria, fungi, or other amebae. In contrast to *Naegleria* and *Acanthamoeba* spp., *Balamuthia* feeds on smaller amebae and protozoa and does not prey on bacteria.

Sappinia diploidea is a species of free-living ameba that is found worldwide and has been isolated from soil, fresh water, forest litter, and

FIG. 223.3 (A) Trophozoite of *Acanthamoeba*. (B) Cyst of *Acanthamoeba* (scanning electron micrograph). (A, From Jager BV, Stamm WP. Brain abscesses caused by free-living amoeba probably of the genus *Hartmannella* living in a patient with Hodgkin disease. *Lancet* 1972;2:1343-5.)

FIG. 223.4 Trophozoite and cyst of *Balamuthia mandrillaris*. (Courtesy Dr. G.S. Visvesvara, Centers for Disease Control and Prevention.)

mammalian feces. The life cycle of this organism involves animal feces. Both the trophozoite and cyst stages are binucleate. The trophozoites are 40 to 80 μm in diameter and can be distinguished by the presence of a large cytoplasmic contractile vacuole and food vacuoles, mitochondria with characteristic tubular crystal patterns, a juxtannuclear Golgi-like network, and a double nucleus.⁵¹ The cyst is round and measures 15 to 30 μm .¹⁶¹

CLINICAL MANIFESTATIONS

Naegleria Fowleri

Primary amebic meningoencephalitis caused by *N. fowleri* is an acute, rapidly progressive illness occurring principally in healthy children and young adults that almost uniformly is fatal. Patients have an abrupt onset of severe bifrontal or bitemporal headache, high fever, nausea and vomiting, malaise, rhinitis, nuchal rigidity and other meningeal signs, neurologic abnormalities, irritability, and other changes in mental status 1 to 15 days after exposure (typically 5 to 8 days), most frequently after swimming or bathing in warm contaminated fresh water.^{45,86,101,134} A history of disturbances of taste and smell has been noted in many cases, although for the most part the early clinical features of primary amebic meningoencephalitis are not distinctive.⁵⁹ Progression from fever to signs of meningitis and encephalitis is unrelenting and rapid. Seizures are common. Coma is present at or develops soon after hospital admission. In the absence of early diagnosis and appropriate treatment, the illness characteristically progresses rapidly to death within 1 week of onset of symptoms (median, 72 hours).⁹ The cause of death is usually from increased intracranial pressure with brain herniation, leading to cardiopulmonary arrest and pulmonary edema.

Other than the clue of a recent history of exposure to warm fresh water, there is little to distinguish primary amebic meningoencephalitis from fulminant bacterial meningitis. A high peripheral polymorphonuclear leukocytosis may be present. CSF findings are similarly nonspecific, with increased pressure, elevated protein level (ranging from 100 mg/100 mL to 1000 mg/100 mL), a normal to low glucose value, and modest polymorphonuclear pleocytosis (ranging from 300 cells/mm³ to as high as 26,000 cells/mm³), but no bacteria, mycobacteria, or fungi are identified on culture. Patients with a suggestive history and CSF indices suggestive of purulent meningitis, but without bacteria on Gram stain, should have a wet mount examined for the presence of motile trophozoites (Fig. 223.5). Smear of the CSF should be stained with Giemsa or Wright stains to identify the trophozoite, if present. The ameba can be clearly differentiated from host cells by the nucleus with its centrally placed large nucleolus.

Acanthamoeba Species

Acanthamoeba spp. and *B. mandrillaris* cause granulomatous amebic encephalitis. The course typically is prolonged, with progression from focal neurologic signs to diffuse meningoencephalitis over weeks to

FIG. 223.5 Brain from a fatal case of *Naegleria* meningoencephalitis. Note the areas of necrosis on the basilar surface.

months after exposure.^{87,130} Patients most susceptible to contracting this disease include very young, old, debilitated, immunosuppressed (HIV/AIDS, organ transplantation), and chronically ill patients (diabetics). The clinical picture resembles that of a bacterial brain abscess or brain tumor, with insidious onset of headache, intermittent low-grade fever, nausea, vomiting, lethargy, stiff neck, and symptoms of increased intracranial pressure. Altered mental status is particularly prominent. As the infection progresses, depending on the area of the brain affected, focal neurologic signs, hemiparesis, drowsiness, aphasia, ataxia, cranial nerve palsies, behavioral and personality changes, and seizures develop. The incubation period after exposure to onset of CNS disease is unknown but is of the order of several weeks to months.

Acanthamoeba skin lesions often have been present for months before the onset of CNS disease. Routine CSF findings frequently are abnormal but nonspecific, with elevated protein level, low glucose value, and, typically, a mononuclear pleocytosis. *Acanthamoeba* spp. also may cause cutaneous, pulmonary, bone, and nasopharyngeal or sinus disease.^{52,83,96} Cutaneous *Acanthamoeba* infection is characterized by pustules, papules, skin ulcerations, and hard erythematous nodules, which develop into nonhealing indurated draining ulcers or subcutaneous abscesses.^{47,87} The most affected sites where lesions occur are the face, trunk, and

extremities. Disseminated disease without CNS involvement has a slightly better prognosis. In patients with AIDS, mortality rates of 70% and 100% are reported for *Acanthamoeba* skin disease alone and in association with CNS disease, respectively.⁶⁹

Acanthamoeba Keratitis

In contrast to its role as an opportunistic pathogen in CNS and skin disease, most cases of *Acanthamoeba* keratitis occur in otherwise healthy individuals who wear contact lenses or who have a history of corneal trauma. Contact lenses of any type, including daily wear and disposable soft and extended-wear lenses, have been implicated in infection. All soft contact lenses contain 50% to 75% water. These lenses can absorb pathogens from contaminated cleaning solutions, carrying cases, and hands. When the lens comes into contact with the contaminated fluid, the amebae quickly adhere to the lens surface. *Acanthamoeba* must be in the trophozoite stage to bind to human corneal epithelial cells. If corneal trauma is present, the organisms invade the corneal tissue and produce parasite-mediated cytolysis of the cornea.⁶⁶ The infection causes destruction of the corneal epithelium and stroma, infiltration of inflammatory cells, and formation of descemetocoele and perforation. The nidus for infection most likely is trauma to the cornea but also may be related to preexisting herpesviral or bacterial conjunctivitis (Fig. 223.6). Amebic keratitis characteristically is painful, progressive, and sight threatening and fails to respond to conventional antibacterial or antiviral treatment.^{5,87} Typically, only one eye is involved; however, bilateral keratitis has been reported. Early symptoms include severe eye pain, lacrimation, foreign body sensation, conjunctival hyperemia, and photophobia. *Acanthamoeba* keratitis frequently is misdiagnosed, initially, as herpetic, bacterial, or fungal infection. The course usually is more indolent, however. Periods of temporary remission delay establishing the diagnosis further. Recurrent corneal epithelial breakdown with dendritic infiltrates progresses to nonsuppurative keratitis, which waxes and wanes over several months and ends in a characteristic ring-shaped stromal abscess with secondary uveitis leading to loss of the cornea.^{5,150} Infection that follows severe trauma deteriorates more rapidly than that which follows contact lens wear. In addition, complications of infection include iritis, cataracts, corneal epithelial ulceration, hypopyon, glaucoma, scleritis, loss of visual acuity, blindness, and penetrating keratitis.⁵

Balamuthia Mandrillaris

B. mandrillaris causes granulomatous encephalitis and cutaneous, sinus, and nasopharyngeal disease.¹³⁰ The portal of entry is skin lesions contaminated by soil, or cysts transported by air currents to the respiratory tract.¹¹⁹ The incubation period of CNS disease is unknown but is thought to be weeks to months (not <10 days).⁹⁷ In animal models, extensive CNS necrosis develops 1 to 3 weeks after inoculation.⁹³ This ameba is known to be extremely encephalotropic and cytopathic, causing extensive damage to the brain tissues. The infection is chronic, and the time between the appearance of skin lesions and neurological symptoms ranges from 1 month to 2 years. Onset of symptoms of granulomatous encephalitis is insidious, with low-grade fever, severe frontal headache, photophobia, nausea and vomiting, meningismus, personality change, and prominent focal neurologic signs that have included cranial nerve palsies, hemiparesis, dysarthria/aphasia, focal seizures, and ataxia.^{7,57} A history of recent otitis was noted by many authors.^{7,57} A slow relentless deterioration to coma and death ensues over several weeks to months (as long as 2 years afterward). Death usually results from cardiorespiratory failure secondary to severe cerebral edema. In many reports, manifestation of cutaneous lesions (facial, nasal, and limb) has preceded development of CNS disease.^{36,63,109,114,163} Although normal CSF parameters have been described in *B. mandrillaris* CNS infection, the typical findings are moderately increased protein levels (may be >1 g/dL), normal or mildly decreased glucose values, and a pleocytosis (about 500 cells/mm³), which commonly but not invariably has a mononuclear predominance.^{7,49,57,93,130}

NEUROIMAGING

Neuroimaging findings in infections caused by free-living amebae are nonspecific and alone do not provide clues to an earlier diagnosis. In

FIG. 223.6 Proposed mechanism for *Acanthamoeba* keratitis. Bacterial contaminants in the water on the lens support the growth of amebae, which leads to an increased number of invading organisms. The organisms adhere to the contact lens and enter tissue through the damaged cornea, with the subsequent development of keratitis.

addition, in the early stages of infection, results of computed tomography (CT) and magnetic resonance imaging (MRI) may be normal. In primary amebic meningoencephalitis, cranial CT and MRI show obliteration of basal cisterns and signs of diffuse brain edema, hydrocephalus, focal and basilar meningeal enhancement, and infarction.^{78,121,137} In granulomatous encephalitis, neuroimaging reveals variable but nondiagnostic abnormalities that include, alone or in combination, discrete corticomedullary lesions; large, solitary, masslike lesions (which may be confused with brain abscess or tumor); large arterial occlusions; and spinal cord infarctions.^{78,121,137} Similarly, in *Balamuthia* infection, neuroimaging is helpful but nondiagnostic; CT scans show a focal enhancing mass or ring-enhancing cystic lesions or both, vascular occlusion, and diffuse edema that frequently progresses to communicating hydrocephalus.^{7,36,57}

MRI shows ring-enhancing lesions or low-density abnormalities mimicking one or multiple space-occupying masses.

PATHOGENESIS

Naegleria trophozoites or cysts enter the body through the nasal cavity by aspiration of water or inhalation of soil. The trophozoites penetrate the olfactory mucosa and, after active phagocytosis by sustentacular neuroepithelial cells of the olfactory nerve, migrate along the nerve, pass through the cribriform plate, and gain entry to the CNS at the level of the olfactory bulbs.^{6,65,97} From the olfactory bulb, which is bathed in CSF and lies in the highly vascularized subarachnoid space, *N. fowleri* disseminate throughout the CSF and CNS. *Naegleria* induce an intense inflammatory response associated with lytic necrosis hemorrhage surrounded by purulent exudates. Numerous superficial hemorrhagic areas also occur in the cortex, around the base of the brain, hypothalamus, midbrain, pons, medulla oblongata, and the upper portion of the spinal cord.^{6,30} Only *Naegleria* trophozoites are found in the CNS lesions. In contrast, most *Acanthamoeba* spp. infections seem to follow hematogenous dissemination from a primary lower respiratory or cutaneous focus.⁹⁷ Researchers have postulated that *Acanthamoeba* spp. are inhaled or inoculated through skin in the cyst phase. *Acanthamoeba* most likely enters the CNS through the blood-brain barrier, particularly through the endothelial lining of cerebral capillaries.^{6,74,95} Less commonly, *Acanthamoeba* is capable of causing CNS infection directly via the olfactory neuroepithelium. The pathogenic mechanisms of infections caused by *B. mandrillaris* are unclear, but it is believed that the organisms migrate either through tissue or via hematogenous spread to the location or locations where disease becomes manifest.⁶ For CNS disease, studies using a mouse model indicate that the organism is inhaled through the nasal passages, adheres to the nasal epithelium, and then travels along the olfactory nerve in to the central nervous system as is seen with both *Naegleria* and *Acanthamoeba*.⁷⁷

Virulence factors described for free-living amebae include the ability to adhere to brain microvascular epithelium, production of extracellular metalloprotease and elastases, release of a pleiotropic cytokine, IL-6, and phagocytosis by food cups or amebostomes.^{1,43,58,75,87,90} Among *Naegleria* spp., pathogenicity is closely related to thermotolerance.³² *N. fowleri*, the only species pathogenic for humans, is unusually thermophilic and can tolerate temperatures of 45°C.¹³⁰ In addition, *N. fowleri* has less demanding growth requirements than nonpathogenic *Naegleria* spp. Trophozoites of pathogenic *Acanthamoeba* spp. also are thermophilic, being able to tolerate temperatures of 37°C, relative to their nonpathogenic counterparts.^{130,128} Thermotolerance seems to be less important for *Acanthamoeba* strains that cause keratitis, presumably because corneal temperatures are lower (32°C–35°C).¹³⁰

PATHOLOGY

Pathologic changes of infection with small free-living amebae are most marked in the CNS. The pathology of primary and granulomatous amebic encephalitis differs fundamentally.⁹⁷ Macroscopically, *N. fowleri* produces diffuse meningoencephalitis, most severely affecting the cortical gray matter. It is characterized by marked cerebral edema and purulent leptomeninges, particularly adjacent to the olfactory bulbs, at the base of the frontal and temporal lobes, and at the hypothalamus.⁹⁴ Frequently, the olfactory bulbs are necrotic and hemorrhagic. Microscopically, an acute mononuclear and polymorphonuclear (PMN) fibrinopurulent leptomeningeal inflammatory infiltrate is seen throughout the cerebrum, brain stem, and cerebellum and the upper spinal cord. Trophozoites tend to concentrate in the perivascular spaces and adventitia of arteries, and they may contain ingested erythrocytes and brain tissue. Large numbers of amebic trophozoites, without the presence of PMNs, are seen within edematous and necrotic neural tissue. Trophic amebae are also seen deep in Virchow-Robin spaces, usually around blood vessels with no inflammatory response. Characteristically, only trophozoites are seen in the CSF or brain tissue.⁹⁷ Presumably, *N. fowleri* cysts are not found in clinical specimens because progression of *Naegleria* infection is so rapid and fatal that the patient dies before transformation from trophozoite into the cyst can occur.⁸⁶

CNS infections caused by *Acanthamoeba* spp. and *B. mandrillaris* are characterized macroscopically by diffuse cerebral edema and hemorrhage, with areas of softening and abscess formation. The meninges are spared except for areas overlying involved cerebrum. Additional areas of hemorrhagic necrosis are concentrated in the posterior fossa, brain stem, cerebellum, midbrain, cerebral cortex, and basal ganglia.^{7,36,37,86} Narrowing of the sulci and flattening of the gyri are noted in areas of active infection. Microscopic changes consist of multinucleated giant cells, with trophozoites and cysts seen within the lesions.⁹⁴ The olfactory bulbs and spinal cord are relatively spared.

Microscopically, necrotizing hemorrhagic encephalitis and subacute or chronic necrotizing granulomatous infiltrates and multinucleate giant cells are scattered throughout the CNS, particularly in the cerebral hemispheres, basal ganglia, midbrain, and brain stem. Typically, trophozoites and cysts of *Acanthamoeba* spp. or *B. mandrillaris* are present within necrotic cerebral tissue, particularly in perivascular spaces. Invasion of blood vessels causes severe necrotizing arteritis and hemorrhagic necrosis. The angiotropic distribution of *Acanthamoeba* or *Balamuthia* infection supports a hematogenous mechanism of spread. In severely immunocompromised patients, the inflammatory reaction may be negligible and lacks a granulomatous component.^{10,93} In the absence of a vigorous granulomatous response, hemorrhagic necrosis that resembles primary amebic meningoencephalitis may occur.¹⁶⁴

Skin lesions of acanthamebiasis and balamuthiasis are characterized by nodules, ulcers, and abscesses and by the presence of amebic trophozoites, cysts, and granulomas in tissue.^{97,96,163} Amebic keratitis is characterized by moderate chronic inflammation of corneal stroma, a mixed polymorphonuclear and lymphocytic infiltrate, and the presence of amebic trophozoites and cysts within the corneal ulcerations.¹⁵⁶

DIAGNOSIS

Previously, most cases of amebic meningoencephalitis were diagnosed with certainty only at autopsy or by brain biopsy.¹⁰ Routine laboratory tests did not distinguish amebic meningoencephalitis from other causes of meningoencephalitis. The first and most important diagnostic step is to recognize the possibility that small free-living amebae may cause infection in the appropriate clinical setting. Among the few reported therapeutic successes, all are notable for early diagnosis and timely institution of appropriate antimicrobial therapy.^{36,71,104,108}

Primary amebic meningoencephalitis should be included in the differential diagnosis of any child or young adult with meningoencephalitis. A history of recent exposure to fresh water should be sought, and a wet mount should be performed on centrifuged CSF. *Naegleria* is isolated most readily from CSF but also may be isolated from brain tissue, particularly olfactory lobes. In contrast, *Acanthamoeba* trophozoites characteristically are absent from CSF, and *B. mandrillaris* has yet to be seen in CSF. *Acanthamoeba* spp. are more likely to be isolated from brain tissue or skin biopsy or from corneal scrapings in cases of keratitis.¹²⁸ Diagnostic techniques include direct microscopy of wet-mount and stained CSF specimens, histologic stains of tissue, fluorescent and immunofluorescent antibody stains of CSF and tissue, direct immunohistochemical stains of tissue, serology, molecular diagnostics, and culture.¹⁵⁵

Direct Microscopic Identification

If amebic infection of the CNS is suspected, a wet-mount preparation of fresh CSF should be examined for the presence of motile amebae.^{86,97,94,155} This method remains the most rapid means of diagnosis. Ideally, the CSF specimen should be kept at room temperature and examined soon after it has been collected. *Naegleria* is particularly fragile. Although the specimen may be kept at 4°C for short periods, it never should be frozen.¹⁵⁵ If present, amebae tend to attach to the test tube wall or surface of the container, so gentle shaking and low centrifugation at 150g for 5 minutes is recommended to dislodge and concentrate the amebae.^{94,155} The supernatant should be placed gently on a slide. The wet mount is examined best by light microscopy under low power (×10 and ×40 objectives), phase-contrast microscopy, or darkfield illumination and may be warmed to promote amebic motility. *Naegleria* trophozoites move in a characteristic “sluglike” fashion by extrusion of a few broad

pseudopodia (lobopodia) anteriorly.¹³⁰ Leftover specimens can be frozen at -20°C for later antigen or antibody testing. Although *N. fowleri* may be shown by histologic stains of fixed CSF smears, Gram stain is not useful because it does not stain amebae and the heat fixation causes lysis.

Naegleria, *Acanthamoeba* spp., and *Balamuthia* may be shown in fixed sections of brain tissue biopsy or autopsy specimens by hematoxylin and eosin, Masson trichrome, periodic acid–Schiff, Wright–Giemsa stain, and Gomori–methenamine silver stains (Fig. 223.7).^{86,87,97,94} Reliably differentiating *Acanthamoeba* and *Balamuthia* by histology alone is difficult. In addition, *Acanthamoeba* trophozoites have been variously mistaken for macrophages or “atypical mononuclear” or epithelial cells on routine histology.^{94,164}

Immunofluorescent stains using monoclonal and polyclonal anti-*Acanthamoeba* and anti-*B. mandrillaris* antibodies (available at the CDC), immunoperoxidase staining, and electron microscopy of tissue sections have been used to confirm the diagnosis (Fig. 223.8).^{36,69,91,155,154} Amebic keratitis may be diagnosed by direct detection of trophozoites or cysts in smears of deep corneal scraping or biopsy using Wright–Giemsa, trichrome, periodic acid–Schiff, calcofluor white, or indirect fluorescent antibody stains.^{86,94,165}

Culture

Culture has a limited role in diagnosis but is useful for confirmation, speciation, and antimicrobial susceptibility testing. *N. fowleri* and *Acanthamoeba* spp. can be cultivated using bacteria as a food source (xenic cultures) or without bacteria, in an enriched cell-free nutrient (axenic) medium that contains antimicrobial agents to inhibit growth of contaminating bacteria.^{27,128,133,155} *N. fowleri* and *Acanthamoeba* spp. are readily cultured from CSF, brain, and lung tissue on various non-nutrient agars or with low concentrations of nutrients, in the presence of a lawn of living or killed bacteria (e.g., most commonly nonmucoid strains of *Escherichia coli* or *Enterobacter* spp.).^{94,128,155} Amebae feed on the lawn of bacteria and grow to cover the plate after 1 to 2 days' incubation at 37°C . Culture plates are incubated at 37°C and examined under low power daily for 10 days.^{94,155}

Amebae can be visualized directly through the back of the inverted agar plate with a conventional microscope under low power.¹²⁸ The characteristic slow, sluglike movement of *Naegleria* trophozoites that is readily seen in a wet mount of CSF is difficult to distinguish on an agar plate.¹²⁸ The ability of *Naegleria* to transform into the flagellated stage after suspension in distilled water is useful diagnostically.^{128,155} Trophozoites of *Acanthamoeba* spp. move slowly by extrusion of multiple, finger-like pseudopodia (acanthopodia).

Culture and isolation of *Balamuthia* is more challenging. Generally, *B. mandrillaris* is more fastidious, does not use bacteria as a food source, grows slowly, and requires a heavily enriched basic medium. *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* all grow vigorously, however, and produce detectable cytopathic effects in mammalian cell cultures (monkey kidney, HeLa, and lung fibroblast tissue), which can be examined for cytopathic effect.^{94,157} Typically, *Balamuthia* grows slowly and may require several weeks to proliferate.¹⁵⁷ Use of a positive control culture is advised to ensure correct methodology and to aid recognition.¹²⁸ In culture, the organism is sensitive to changes in osmolarity and does not readily tolerate either hypoosmotic or hyperosmotic conditions. *Sappinia diploidea* can be cultivated on non-nutrient agar plates coated with bacteria.

Although no outbreaks of infection in laboratory workers caused by free-living amebae have been reported, care must be taken when handling specimens to avoid getting culture materials on skin and in cuts or abrasions. Specimens should be handled in a biologic safety cabinet by technologists wearing masks and gloves.^{94,155}

Serology

Although specific *N. fowleri* antibody has been shown in survivors of primary encephalitis, serologic tests are of no use diagnostically.¹³⁴ Onset of primary amebic meningoencephalitis is rapid, and almost all patients die before significant antibody production can occur. In contrast, because the clinical courses of *Acanthamoeba* spp. and *B. mandrillaris* infections usually are chronic, robust antibody responses have time to develop. Detection of serum or CSF antibody against *Acanthamoeba* spp. or *Balamuthia* by indirect immunofluorescence staining has helped establish the diagnosis in many cases.^{36,70,130,149} By this method, amebae fixed on a slide bind antibody present in the patient's serum or CSF, which then is detected by fluorescein-conjugated anti-human antibody.

Serologic testing has been most useful as an epidemiologic tool. Although the incidence of infection with free-living amebae seems low, results of seroepidemiology studies suggest that human exposure to amebae occurs frequently. Sera from healthy adults and children contain antibody against *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris*.^{31,61,88,124,127} Detection of antibodies to *N. fowleri* and *Acanthamoeba* spp. in asymptomatic adult and pediatric populations from North Carolina, Virginia, and Pennsylvania in the United States and from Czechoslovakia and New Zealand presumably reflects unavoidable environmental contact with these ubiquitous organisms.^{20,88} All specimens from a group of 93 asymptomatic patients from New Zealand contained anti-*Naegleria* and anti-*Acanthamoeba* IgG and IgM antibodies.³¹ Antibodies were neutralizing against *Acanthamoeba* spp. but not against *N. fowleri*. In virtually all cases of infection caused by *Acanthamoeba* spp., disease occurs in the setting of immunocompromise or in an immunologically privileged site, such as the cornea. Whether neutralizing

antibodies play a role in the very low incidence of infections in healthy individuals, despite seemingly frequent environmental exposure, is unknown.

Immunofluorescent antibody staining of serum for antibodies against *Acanthamoeba* spp. and *B. mandrillaris* has proved to be a rapid non-invasive diagnostic test in many clinical cases.^{39,70,165} Potentially, this test may be useful clinically for establishing an earlier definitive diagnosis and initiation of therapy. Because the presence of *Balamuthia* antibodies may represent asymptomatic environmental exposure, confirmation of results of immunofluorescent antibody testing by histology, indirect immunofluorescent staining of tissue, or polymerase chain reaction (PCR) of CSF is advised. More recently, immunofluorescent antibody staining of serum from patients with encephalitis, predominantly from California, revealed seven previously unrecognized or misdiagnosed cases of *Balamuthia* and one case of *Acanthamoeba* encephalitis.¹²⁷ Most serum specimens showed some evidence of antibody (<1:64), which was attributed to cross-reactivity or subclinical exposure to contaminated soil. A cutoff value of greater than 1:64 for *Balamuthia* serology was considered positive pending results of confirmatory tests (e.g., histology, immunohistochemistry, or PCR).¹²⁷ Low levels of antibody may reflect preceding subacute disease or contact with environmental amebae.¹²⁷

Molecular Diagnostics

Although microscopic assessment of a wet-mount preparation or histology may be useful in experienced hands, definitive identification in most centers awaits results of specimens sent out for immunofluorescence tests. Advances in molecular diagnostics offer the real possibility, however, of sensitive, specific, and rapid diagnosis being made by any laboratory with the capability to perform PCR. PCR of DNA extracted from frozen brain tissue has been used to confirm *N. fowleri* infection diagnosed by histopathology and immunofluorescent staining.²⁵ Similarly, nested and real-time PCR provide rapid, sensitive, and specific screening of environmental and recreational water sources for the presence of *N. fowleri*.^{89,115} PCR, using mitochondrial 16S rRNA gene DNA as the target, has been used to detect *B. mandrillaris* in clinical samples of CSF and formalin-fixed brain and lung tissue of patients with encephalitis.^{144,167} These assays have the ability to detect a single ameba per reaction mixture.¹⁶⁷

The development of a multiplex real-time PCR assay for simultaneous detection of *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* in clinical specimens of CSF and brain tissue offers the possibility of highly sensitive and specific rapid confirmatory diagnosis of CNS infection by free-living amebae and the chance of initiating earlier, more effective treatment.¹¹² The assay is sensitive down to detection of a single ameba in a specimen and is species specific for *N. fowleri* and *B. mandrillaris* and genus specific for *Acanthamoeba*.^{33,112} A recently developed real-time multiplex PCR assay identifies *N. fowleri* DNA in the CSF and brain tissue samples obtained from primary amebic encephalitis patients antemortem. This test identifies all three genotypes known to be present in the United States. The time taken to identify *N. fowleri* from the time the specimen arrives in the laboratory is about 5 hours and can be cut down to 2 hours if the specimen is CSF.¹¹²

Finally, the development and use of metagenomic deep sequencing for the diagnosis of *Balamuthia mandrillaris* encephalitis and other unusual or novel organisms that may cause encephalitis is a powerful diagnostic tool that has the potential for rapid and precise identification of pathogens. This will allow for the initiation of treatment earlier in the course of the patient's illness, improving patient outcome.¹⁶⁶

TREATMENT

Mortality among patients with primary and granulomatous amebic encephalitis is greater than 95%.^{9,131} Indeed, there are only a handful of known survivors of primary amebic meningoencephalitis.^{23,24,59} The high fatality rate undoubtedly is due partly to late diagnosis or misdiagnosis and late initiation of potentially effective treatment. Inclusion of amebic infection in the differential diagnosis, in the appropriate clinical setting, and timely administration of effective antiamebic treatment are emphasized in successful cases.^{13,108} In the future, availability of real-time PCR may facilitate accurately establishing an early diagnosis.

Although no randomized trials of optimal treatment for infection caused by free-living amebae have been performed, potentially effective treatment is available if the condition is recognized early.

If infection is suspected, treatment should not be withheld pending the results of confirmatory testing. Treatment regimens are based on results of in vitro susceptibility, in vivo animal experiments, and empirical treatment of individual cases. If amebic infection is suspected, accurate determination of the species is important to ensure optimal treatment. No one drug is effective against all free-living amebae (e.g., amphotericin is the drug of choice for *N. fowleri* infection but is neither amebistatic nor amebicidal for *Acanthamoeba* spp. and varies in its efficacy against *Balamuthia*).^{40,129} Previously, authors have suggested initiating treatment with a combination of agents such as amphotericin B and flucytosine; pentamidine with sulfadiazine, clarithromycin, an azole compound, and flucytosine; flucytosine with an azole compound, azithromycin, pentamidine, and sulfadiazine; and pentamidine, an azole compound, sulfadiazine, amphotericin B, azithromycin, and rifampicin, which have activity against *Naegleria* and *Acanthamoeba* or *Balamuthia*, until amebae can be identified definitively.^{36,98,153,164} Among newer antibiotics, miltefosine and voriconazole are potentially attractive as treatments for infection caused by free-living amebae. Both drugs penetrate brain tissue and have a low toxicity profile. Although differences in susceptibility exist among strains, voriconazole has activity in vitro against *Acanthamoeba* spp. and *N. fowleri*, whereas miltefosine has in vitro activity against *Acanthamoeba* spp. and *Balamuthia*.¹²⁶ Miltefosine is currently available via expanded access IND directly from the Centers for Disease Control and Prevention (CDC) in the United States for the treatment of infections with free-living amebae.¹⁷

Amebic Meningoencephalitis

N. fowleri is exquisitely susceptible in vitro to amphotericin B, which remains the treatment of choice for primary amebic meningoencephalitis.¹³¹ All successfully treated cases have included amphotericin B in the treatment regimen. *Naegleria* also is susceptible in vitro to azithromycin and miconazole, with synergism in vitro and in the animal model with the combination of amphotericin and miconazole or tetracycline.^{40,53,134,140,151} Treatment regimens in cases with successful outcomes have included intravenous amphotericin, high-dose intravenous and intrathecal amphotericin and miconazole, oral rifampin, intravenous sulfoxazole, and intravenous and intrathecal amphotericin in combination with oral rifampin.^{4,13,134} In at least one reported case, intravenous and intrathecal amphotericin B was combined with intravenous and intrathecal miconazole and with oral rifampin.⁵⁹ Rifampin has yielded conflicting results in in vitro testing.⁵⁴ Liposomal amphotericin B seems less effective in vitro and in the animal model than conventional amphotericin (10-fold higher minimum inhibitory concentration) and is not recommended.⁵⁴ Promising results in mice have been reported with chlorpromazine and to a lesser extent miltefosine and voriconazole.¹⁵⁴ In contrast to *Acanthamoeba* spp. and *B. mandrillaris*, *N. fowleri* remains a trophozoite and does not encyst in tissues, so after it is destroyed by antimicrobial therapy, infection with *N. fowleri* should not recur.

Optimal treatment for CNS disease caused by *Acanthamoeba* spp. has not been established, and the prognosis remains grim, with few reports of survivors.¹³¹ Most cases are diagnosed at autopsy or a few days before death, leaving little time to evaluate treatment. Treatment successes have been attributed to initiation of treatment before spread of infection into the CNS. Combination treatment is favored because no single drug is active against trophozoites and cysts, and many drugs are amebistatic rather than amebicidal.⁸⁷ Among the few reports of successful treatment, orally administered trimethoprim-sulfamethoxazole, ketoconazole, and rifampin were associated with a favorable outcome in two apparently immunocompetent children with CNS disease.¹³⁸ Fluconazole, rifampin, metronidazole, and sulfadiazine were used successfully in a 64-year-old immunocompetent host with early disease.¹⁰⁸ Still other regimens have included pentamidine isethionate, 5-fluorocytosine, and itraconazole.¹⁵⁴

Similarly, Slater and colleagues¹³⁹ reported successful treatment of disseminated cutaneous acanthamebiasis in a renal transplant recipient using 4 weeks of intravenous pentamidine, topical chlorhexidine, and

2% ketoconazole followed by maintenance oral itraconazole. A combination of pentamidine, 5-fluorocytosine, itraconazole, and topical chlorhexidine gluconate/ketoconazole cream was used to treat disseminated acanthamebiasis successfully in a lung transplant recipient.¹⁰⁶ Pentamidine is considered the most suitable treatment before CNS invasion has occurred because of its low penetration into the CNS. Because of its low penetration across the blood-brain barrier and nephrotoxicity, 5-fluorocytosine was preferred to pentamidine for CNS infection and in renal transplant recipients.^{40,87} The anti-*Leishmania* drug miltefosine has been found to be useful both for systemic infections and for amebic keratitis.¹⁵⁴

Optimal treatment for *B. mandrillaris* infection also remains to be determined. Reports of successful treatment for granulomatous encephalitis caused by *Balamuthia* based on empirical regimens are few. If it is recognized early in its course, however, a more favorable outcome apparently is possible. According to Visvesvara, in the 100 cases reported only seven patients have survived, including four patients treated with a combination of flucytosine, pentamidine isethionate, fluconazole, sulfadiazine, and a macrolide such as azithromycin switched to clarithromycin (better CSF penetration), whereas some patients also received a phenothiazine (thioridazine or trifluoperazine).^{36,154} Pentamidine treatment frequently was discontinued or interrupted because of side effects. Treatment failures have been reported in patients treated with similar regimens, however, possibly because of late initiation of treatment.⁴⁹ Pentamidine and azithromycin were more effective in vitro than fluconazole, flucytosine, or sulfasalazine.¹³¹ Some researchers have postulated, however, that some of these drugs may be synergistic in vivo.¹³¹ Because of concern about reactivation from dormant cysts in the brain, both patients remained on long-term fluconazole and on sulfadiazine or clarithromycin prophylaxis. The drug miltefosine has also been used. One patient underwent excision of a brain abscess while undergoing treatment.

Use of corticosteroids to treat cerebral edema and inflammation seems to exacerbate *Acanthamoeba* infection. A precipitous decline in the clinical condition of one patient has been reported after administration of corticosteroid therapy.⁴⁹ At present, the risk of corticosteroid treatment probably outweighs any potential benefit and is best avoided.^{49,87,117}

Amebic Keratitis

If untreated, amebic keratitis invariably progresses to visual loss and enucleation. Although amebic keratitis is more amenable to antimicrobial treatment than systemic infection, treating it is still difficult. The presence of *Acanthamoeba* cysts in deeper corneal layers renders exposure to adequate drug levels problematic. In addition, *Acanthamoeba* cysts are resistant to most antibacterial agents at concentrations that are achievable but nontoxic to the cornea. As with systemic infection, establishing the diagnosis early is required for treatment to be most effective.

In the early stages of infection, prolonged frequent application of drug is recommended. Combination treatment is preferred during prolonged treatment because of concerns for development of resistance. Nonetheless, cures have been reported with a variety of topical agents; the cationic antiseptic chlorhexidine gluconate and 0.02% polyhexamethylene biguanide (PHMB), a swimming pool disinfectant, alone or in combination with propamidine are among the drugs of choice for amebic keratitis.^{42,81,131,132} Both drugs are effective against trophozoites and are well tolerated in the eye.⁸¹ Alternatively, two diamidines, propamidine isethionate and hexamidine, can be used, or chlorhexidine can be used along with diamidine.¹⁵⁴ Visvesvara reports that they should be used hourly as drops day and night for 48 hours initially, followed by hourly drops by day only for another 72 hours and, then, because of epithelial toxicity, tapered to 2 hours by day 5 for 3 to 4 weeks. Neomycin and oral azoles (e.g., miconazole or itraconazole) also have proved useful. Newer agents, such as myristamidopropyl dimethylamine and miltefosine, are effective *Acanthamoeba* cysticidal agents, possess excellent antifungal and antibacterial activity and show promise in treating recalcitrant keratitis.^{62,122,131}

Many cases of keratitis, particularly when chronic or where medical treatment alone fails, require keratoplasty and corneal grafting. In these cases, prolonged medical treatment aims to cure or control disease to

allow for successful transplantation. Timing of surgery is controversial. Antiamebic drugs usually are continued for months after surgery to prevent late excystation of residual dormant cysts.³ Use of topical or systemic corticosteroid to treat severe pain or inflammation is controversial. Severe complications have been described in clinical cases, and dexamethasone induces encystment and increases cytopathogenicity of emerging trophozoites in animal models.^{100,145}

ROLE OF ACANTHAMOEBA SPECIES AS RESERVOIRS OF INTRACELLULAR PATHOGENS

Although most bacteria are prey for free-living amebae, some bacteria have evolved to survive uptake by amebae. Many *Acanthamoeba* spp. act as environmental reservoirs of recognized intracellular pathogens for humans, including *Coxiella burnetii*, *Legionella pneumophila*, *Mycobacterium* spp., *Pseudomonas aeruginosa*, and *Cryptococcus neoformans*, and for potential emerging pathogens, such as *Rickettsia*-like organisms and *Parachlamydia* spp.^{56,55,60,92,147} Some ameba-resistant microorganisms coexist with amebae as endobacterial symbionts, whereas others exploit the amebae as hosts for survival, for multiplication, or as vectors of disease.⁸ Free-living amebae act as a “Trojan horse” in the transmission of bacterial passengers, such as for *L. pneumophila* or *M. avium*, or as an “evolutionary crib” for the selection of virulence traits and for adaptation of microorganisms to life within human macrophages, such as for *C. neoformans*.^{8,56}

For *L. pneumophila*, prior multiplication within free-living amebae, principally *Acanthamoeba* spp., seems to be a prerequisite for acquisition of infection in humans.¹⁴⁶ In addition, many bacteria, such as *M. avium*, survive protected from chlorination, biocides, antibiotics, and desiccation within ameba cysts.^{91,144} Similarly, growth of *M. avium* in amebae results in enhanced survival in macrophages. Researchers also have postulated that free-living amebae may have adapted some microorganisms for successful intracellular survival within macrophages.^{50,141} Free-living amebae also apparently promote virulence traits and antimicrobial resistance in *L. pneumophila*, *M. avium*, and *C. neoformans*.^{21,22,103} Researchers have postulated that capsule formation evolved in *C. neoformans* in response to selective pressure to resist environmental amebae. Production and maintenance of a capsule allows *Cryptococcus* to survive in human macrophages.¹⁴¹ Some microorganisms resistant to amebae seem to behave as endosymbionts and to influence development and maintenance of virulence traits that enhance pathogenicity of free-living amebae.^{48,56} Clinical and environmental *Naegleria* spp. do not support bacterial endosymbionts.

PREVENTION

Infections caused by free-living amebae are reported to be characterized by an absence of distinguishing symptoms, delayed diagnosis or misdiagnosis, and an almost uniformly poor prognosis without early appropriate treatment. Prevention of infection is of paramount importance. Strategies to prevent *Naegleria* infection exist; *N. fowleri* is susceptible to 1 µg/mL or less of chlorine, and adequate chlorination of water in swimming pools or hot tubs is a simple and sensible preventive measure. If water temperatures are higher, use of increased concentrations of chlorine (>2 to 3 mg/L) is recommended.⁹⁷ In certain parts of the world, environmental levels of *N. fowleri* are monitored to ensure that it is safe to swim and that the probability of acquiring an infection is low.¹⁵ A prudent measure is to educate the public on the potential dangers associated with exposure to warm bodies of fresh or thermally polluted water, especially when temperatures are high and water levels are low, and to avoid immersion, diving, jumping, or horseplay that might force water up the nasal passages or disturb sediment.¹⁶⁸ If a neti pot is used for nasal irrigation, only bottled or filtered water should be used.

Prevention of infection caused by *Acanthamoeba* spp. or *B. mandrillaris* is problematic and involves regular inspections of hot-water tanks, plumbing, and eye-wash stations. *Acanthamoeba* keratitis associated with use of contact lenses is preventable, however. Contact lens wearers should be aware of the importance of proper care of the lenses. Lenses should be cleansed in sterile benzalkonium-preserved saline or disinfected

by heat. Use of homemade cleansing solutions and wearing lenses while swimming are contraindicated.

Although the incidence of infections caused by free-living amoebae is small at present, the number of these infections is likely to grow with increasing numbers of transplant patients and patients with AIDS. Similarly, some researchers have predicted that climate change associated with global warming may further increase the numbers of free-living amoebae in the environment.²⁵

Toxoplasmosis

Kenneth M. Boyer • Santhosh M. Nadipuram

Toxoplasma gondii is an obligate intracellular protozoan parasite (phylum Apicomplexa, class Sporozoa, order Eucoccidiiida).^{195,204,254} It is the only species in the genus. Infection may be clinically inapparent or latent, or it may result in actual disease, called toxoplasmosis. Latent *Toxoplasma* infection is common, involving approximately a third of the world's population. Overt toxoplasmosis is relatively uncommon and ranges in severity from subtle, self-limited disease to devastating and life-threatening illness.

Toxoplasma gondii was observed first in 1908 by Nicolle and Manceaux^{70,186} in mononuclear cells in the spleen and liver of a North African rodent, the gundi (*Ctenodactylus gundi*). The organism soon was identified as a cause of disease in other animals, and in 1923 Janku¹¹⁵ first recognized a case in a human. He described a parasite found in the retina of an infant; it was recognized later by Levaditi¹³⁹ as *Toxoplasma*. In 1937, Wolf and Cowen²⁶¹ reported a case of congenital granulomatous encephalitis that they considered to be caused by an "encephalitozoon."

Albert Sabin,^{216,217} who previously had encountered *T. gondii* in virologic work in guinea pigs, made the correct diagnosis of congenital toxoplasmosis in this case, and it was confirmed by serial passage of the parasite in laboratory animals.²⁶²

The discovery of *Toxoplasma* as a cause of disease acquired later in life has been credited to Pinkerton and Weinman,¹⁹⁷ who in 1940 described a generalized fatal illness caused by this organism in a young man. In retrospect, a case of acquired toxoplasmosis had been reported in 1908 by Darling.⁵⁶ In 1948, Sabin and Feldman²¹⁵ described a serologic test, the dye test, that allowed numerous investigators to study the epidemiologic and clinical aspects of toxoplasmosis and to define the spectrum of disease in humans. In 1969, some 60 years after the parasite was discovered, Frenkel, Dubey, and Miller^{73,83-85} established that *Toxoplasma* is a coccidian protozoan and that its definitive hosts are the domestic cat and related members of the felid family.

ORGANISM AND TRANSMISSION

T. gondii exists in three forms or stages: the proliferative stage, or tachyzoite; the latent stage, a tissue cyst that contains bradyzoites; and a sexual form, the oocyst, within which sporozoites develop. The oocyst is formed during the intestinal epithelial stage of infection, exclusively in members of the cat family, the definitive host. The tachyzoite and tissue cyst are found in the extraintestinal tissues of cats and also in

many other mammalian and avian hosts. Each stage of the organism has antigens in common with the other stages as well as unique antigens. Many of these antigens have been cloned, sequenced, and localized to microanatomic structures.^{168,254} Humans may become infected from any of the three forms, as detailed later.

The tachyzoite form (Fig. 224.1A–C) is crescent shaped or oval, is approximately 3 by 7 μm , and is seen during the acute stage of infection. It stains well with Wright or Giemsa stain. Ultrastructural features

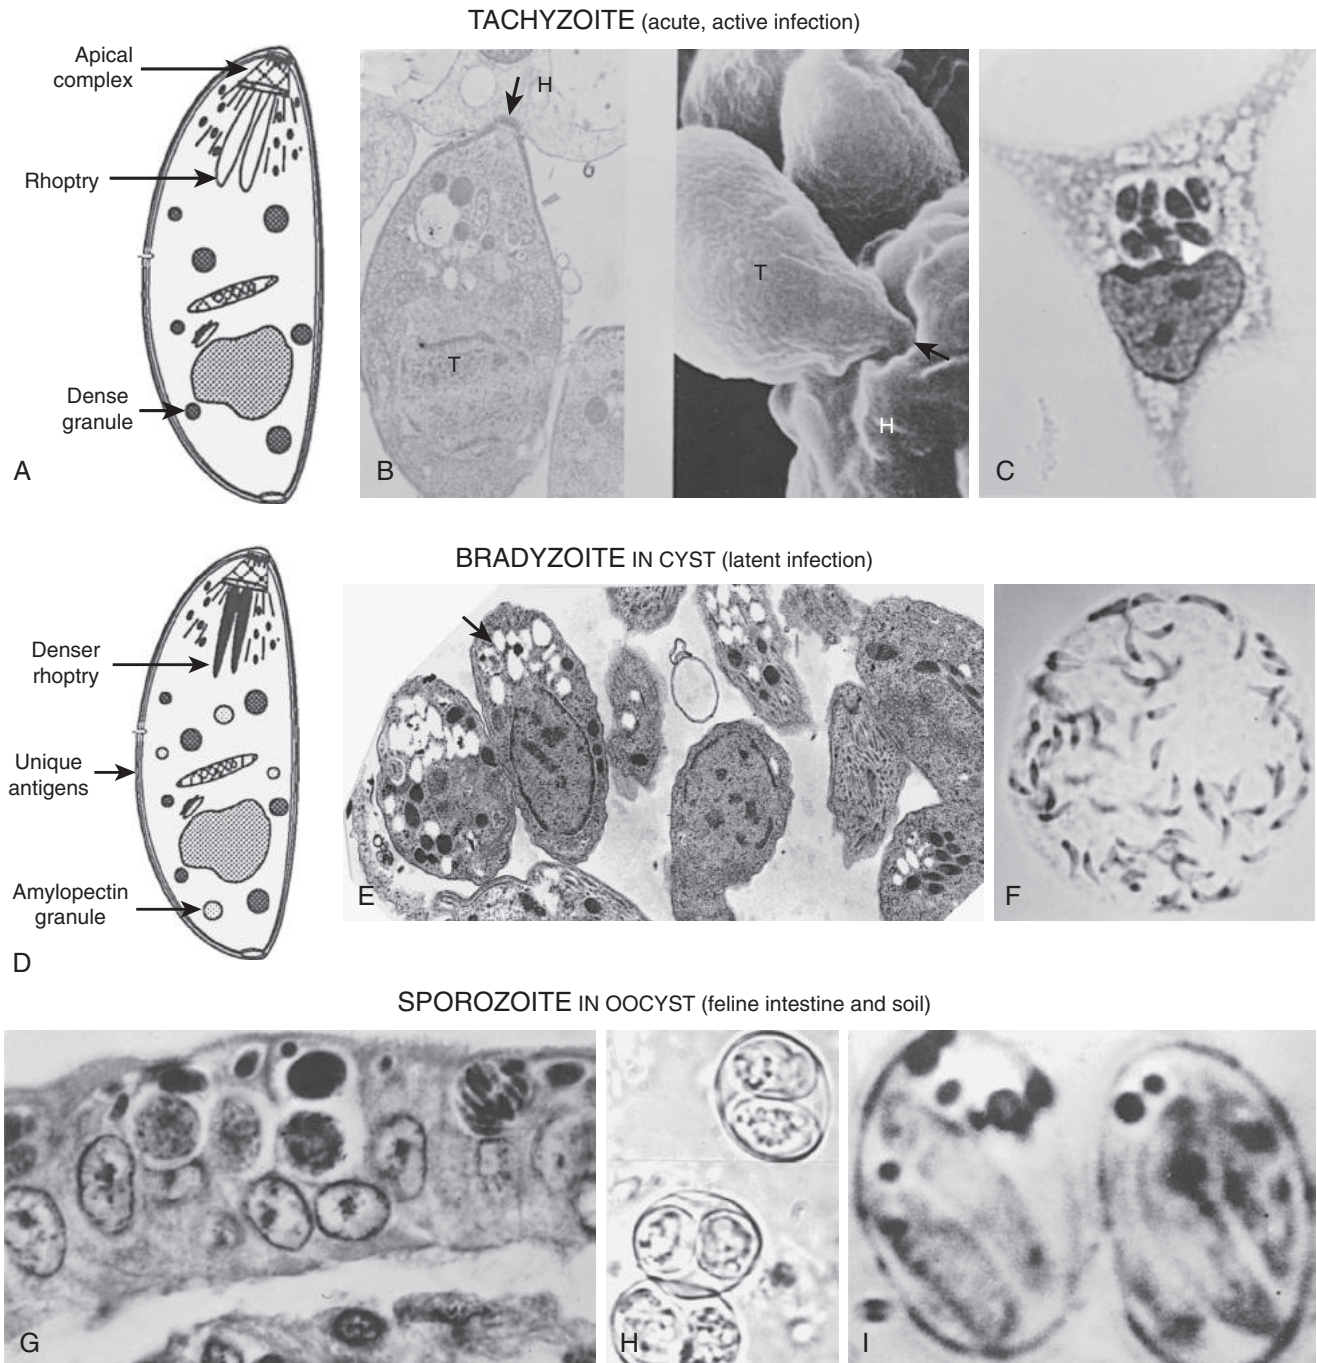

FIG. 224.1 Stages of *Toxoplasma gondii*. (A) Schematic diagram of a tachyzoite. (B) Transmission and scanning electron micrographs of a tachyzoite (*T*) invading a host cell (*H*). Arrow indicates invagination of the host cell at the point of invasion. (C) Light micrograph of tachyzoites replicating within a parasitiferous vacuole in the host cell cytoplasm. (D) Schematic diagram of a bradyzoite. (E) Transmission electron micrograph of a cyst containing bradyzoites (arrow indicates amylopectin granules). (F) Light micrograph of a cyst containing bradyzoites. (G) Development of oocysts in cat intestine. (H) Oocysts in the lumen of cat intestine. (I) Sporulating oocysts that contain sporozoites. A, Apical complex; H, host cell; T, tachyzoite. (From Boyer KM, McLeod RL. *Toxoplasma gondii* [toxoplasmosis]. In: Long SS, Pickering LK, Prober CG, editors. *Principles and Practice of Pediatric Infectious Diseases*. New York: Churchill Livingstone; 1997:1423.)

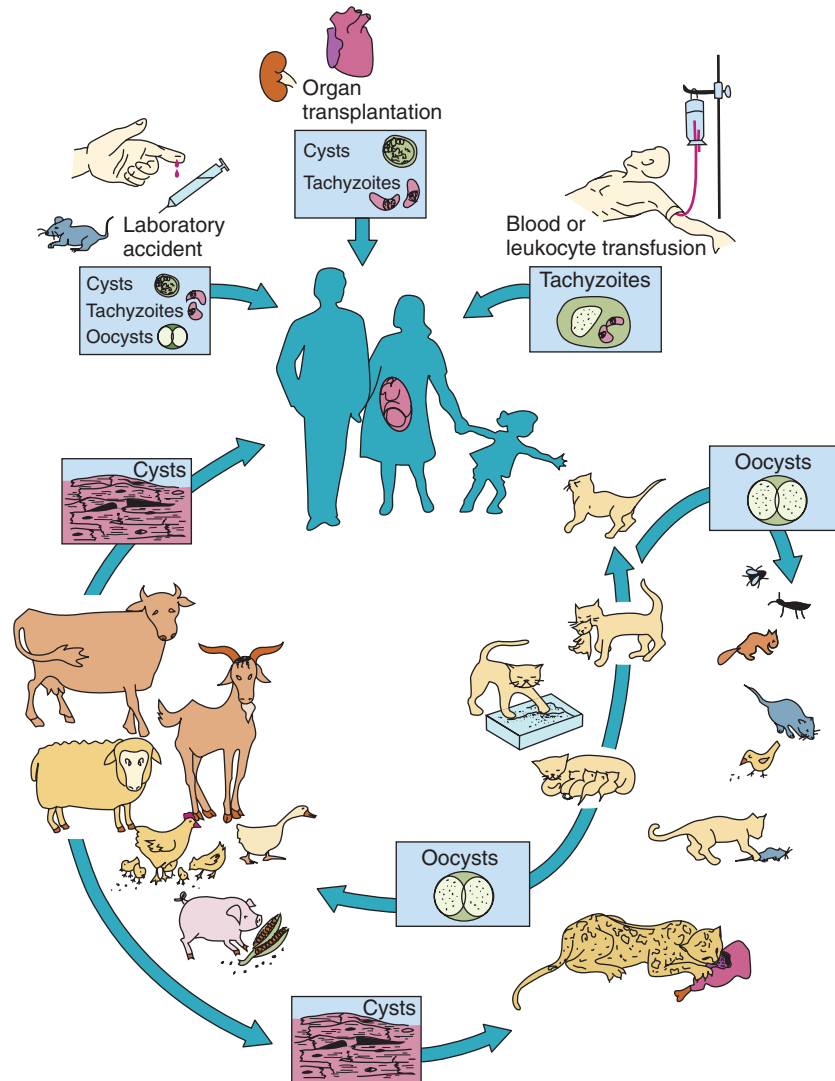

FIG. 224.2 Life cycle of *Toxoplasma gondii*. Cats are definitive hosts, with humans and other mammals being intermediate hosts. (From Remington JS, McLeod R. Toxoplasmosis. In: Braude AI, editor. *International Textbook of Medicine: Medical Microbiology and Infectious Disease*. vol. II. Philadelphia: Saunders; 1981:1818.)

include the apical complex of microtubules and rings, secretory organelles called rhoptries, micronemes and dense granules, and a chloroplast-like structure, called the apicoplast, with its own unique DNA.^{36,74,254} Tachyzoites can invade all mammalian cells except perhaps nonnucleated red blood cells. They cannot withstand freezing and thawing, desiccation, or brief exposure to gastric or duodenal digestive juices. After penetration occurs, the tachyzoite multiplies by endodyogeny within a nonfusogenic vacuole, ultimately causing disruption of the cell and cell death. Hematogenous spread of tachyzoites to the placenta with secondary spread to the fetus results in congenital toxoplasmosis in humans and fetal infection and abortion in other susceptible animals.

The bradyzoite (see Fig. 224.1D–F) is able to persist in encysted form in all tissues and cause a chronic (latent) infection for the entire lifespan of the infected host. Cysts are demonstrable in tissues the first week of infection and range in size from approximately 10 to 100 μm . They have an argyrophilic wall but stand out most clearly from surrounding tissue when stained with periodic acid–Schiff stain. Usually, no inflammatory reaction occurs around cysts. Because this form can persist for many years in the tissues of clinically normal children and adults, its demonstration in histologic sections does not signify recent infection. Peptic or tryptic digestive fluids immediately disrupt the cyst wall, but the liberated bradyzoites (which have apical nuclei but otherwise resemble the tachyzoite form under light microscopy) can survive in

these fluids for several hours, which allows time for invasion of local cells. Cysts can be destroyed by heating to 66°C (150°F), by freezing (below –20°C [–4°F]) and thawing, and by desiccation. They can survive for some months at refrigeration temperatures (4°C [39°F]) if they are in tissue. Infection in humans may be acquired by eating raw or inadequately cooked meat that contains cysts (Fig. 224.2). In carnivorous animals, infection may be acquired by eating raw meat or prey species that contain encysted organisms.

The oocyst form (see Fig. 224.1G–I) is found only in feces of members of the cat family (from household cats to mountain lions), the definitive hosts for *Toxoplasma*, and is the result of sexual reproduction (gametogony and schizogony), which occurs in the intestinal epithelium.^{85,109} Oocysts are ovoid and approximately 10 to 12 μm . Infected cats may shed 10 million oocysts each day, which may be excreted for 3 weeks after primary (acute) infection but rarely thereafter. Excreted oocysts become infectious only after they undergo sporulation (eight sporozoites form in each oocyst); sporulation occurs 1 to 21 days (most commonly 2–8 days) after excretion, depending on temperature and the availability of oxygen. The oocyst is far more resilient than the other life cycle forms and can survive for months in water and for 1 year or more in moist soil. Ingestion of sporulated oocysts transmits the infection. Oocysts play a major role in transmission by the fecal–oral route in animal reservoirs and by inadvertent ingestion in humans.

The genome of *T. gondii* consists of 8×10^7 base pairs distributed among 12 chromosomes. Much of the genome has been sequenced, a genetic linkage map has been constructed, and three major clonal genotypes (I, II, and III) have been identified.^{55,107,130,144,226,254} Some of the factors that regulate stage conversion from tachyzoite to bradyzoite have been defined.^{168,254} Understanding of the regulation of life cycle stages and the unique pathways of intermediary metabolism in *T. gondii* and related apicomplexans (e.g. *Plasmodium*) may provide new approaches to therapy.

EPIDEMIOLOGY

Acquired Infection

Cats are central in the parasite's life cycle, and humans and other mammals are intermediate hosts. If infected tissue (e.g., a mouse) is consumed by a susceptible cat, the sexual cycle is induced in the cat intestine; oocysts are excreted and are infectious for mammals and birds, in which the life cycle (tachyzoites and encysted bradyzoites) is perpetuated. Cats shed oocysts for only brief durations (days to weeks) but in extremely large numbers (1×10^7 /day). A cat is more likely to become infected if it is an outdoor (feral) cat or a predator or is fed fresh, uncooked table scraps. Humans come in contact with cat excrement either directly (e.g., emptying the litter pan, eating uncooked vegetables) or by more insidious means (e.g., cleaning a horse stall, weeding the garden, playing in a sandbox). Accidental ingestion may occur under circumstances that are unsuspected. In a recent report, only 49% of women with acute primary toxoplasmosis during pregnancy who gave birth to infected children could identify significant risk factors for sporozoite acquisition, although 78% had humoral antibodies against sporozoites.²²

Meat for human consumption that contains tissue cysts may also serve as a source of infection if it is eaten raw or undercooked. Examples of inadvertent exposures include an Amish farm wife preparing sausage, a couple consuming steak tartare in an expensive restaurant, and a rancher butchering a deer.²² Mode of infection probably varies internationally according to climate, cultural, dietary, and soil exposure practices. In Chile, for example, 43% of women with recent infection had antibody to sporozoite-specific protein (oocysts), suggesting ingestion of undercooked infected meat as the more common mode of acquisition.¹⁸¹

Infection with *Toxoplasma* occurs commonly in humans. It is estimated that 2 billion of the world's population are infected.¹⁹⁵ In the United States, the prevalence of seropositivity (synonymous with latent infection) has been determined from studies of military recruits, from surveys in major cities, and most comprehensively from the National Health and Nutrition Examination Surveys (NHANES). In the early 1960s, the overall prevalence in military recruits was 14%, with the lowest rates in the Mountain (3%) and Pacific (8%) states and the highest rates in the Northeast (20%) and East South Central (19%) states.²²⁸ A more recent study from the late 1980s showed a similar geographic distribution, but prevalence rates were approximately a third lower throughout the country.²²⁸

The NHANES are periodic cluster sample surveys representing the entire population of the United States. The 1988 to 1994 NHANES showed an overall seroprevalence in individuals of childbearing age (12–49 years old) of 14.1% compared with rates of 9.0% for the same age cohort in the 1999 to 2004 NHANES¹²¹ and 6.7% in the 2009 to 2010 study.¹²⁰ Higher prevalences of *Toxoplasma* infection in the United States are associated with foreign birth, low educational level, living in crowded conditions, and having a soil-related occupation.¹²²

Dietary exposure is probably a declining mode of acquisition in the United States.¹²² Previous estimates were that approximately 8% of commercial beef, 20% of commercial pork, and 25% of commercial lamb contained encysted *Toxoplasma* bradyzoites.¹⁷⁹ More recent data suggest much lower levels of viable tissue cysts in commercial meat, although “free range” and “organic” meats have higher prevalences.^{72,101,118} An indirect mechanism of exposure to cysts derived from livestock, especially goats and sheep, is consumption of unpasteurized dairy products such as raw milk and cheese.²¹⁸ A “niche” meat source with high prevalence of *Toxoplasma* infection is game. Studies in Ohio yielded

prevalences of 73% to 76% in white-tailed deer.⁷¹ We are aware of two “miniepidemics” of acute toxoplasmosis (including congenital infections) related to consumption of deer and elk “tartare.”

During these decades of declining prevalence of *Toxoplasma* infection, the rate of cat ownership has actually increased in the United States.^{121,122} The net overall decline in prevalence may be explained partly by improved agricultural safety, but also by the common practice of freezing commercial meat before releasing it for sale. Combined with the use of home freezers, these practices may be having a significant beneficial effect.^{101,118}

Additional modes of transmission, such as waterborne,^{12,20,69} have been described. Their exact contribution to the overall prevalence of toxoplasmosis in the United States is unclear, however. During the decades of the NHANES studies, increasing proportions of US water supplies have added filtration to decrease *Giardia* and *Cryptosporidium* transmission. This filtration also is likely to eliminate *Toxoplasma* oocysts.¹²²

Internationally, prevalence rates vary considerably. Rates in studies include the following: United Kingdom, 9%; China, 11%; Poland, 41%; France, 44%; Belgium, 49%; and Brazil, 60% to 77%.^{192,195,240} The prevalence of infection is determined partly by climate; colder regions and regions that are hot and dry or at high altitude have lower rates of human infection than warmer and moister regions do. Prevalences are declining in Europe, notably in France,¹⁸⁸ because of educational efforts and improved meat safety. Tropical South American countries, particularly Brazil, continue to have high prevalences, with correspondingly high rates of congenital and ocular infection.^{2,18,31,58,128,227,243}

Despite declining prevalence in the United States, it is estimated that more than 1 million new infections occur each year, with resultant ocular lesions in more than 21,500 persons, of which approximately 4800 are symptomatic.¹¹⁹ An analysis of International Classification of Diseases, Ninth Revision (ICD-9) codes in private insurance records resulted in an estimate of 6856 cases per year.¹⁴⁹ The rate of hospitalization for human immunodeficiency virus (HIV)–associated toxoplasmosis has declined since the advent of effective antiretroviral therapy; however, hospitalization for non-HIV-associated toxoplasmosis has remained steady from 1993 to 2008.¹²³

Common-source outbreaks of acute acquired *Toxoplasma* infection have been authenticated. Unique and clear-cut sources that have been documented to be highly likely include exposure to contaminated municipal water systems,^{20,58} aerosolized cat excrement in a riding stable,²³⁸ and consumption of unpasteurized goat milk.²¹⁸ In other circumstances, extensive investigations have failed to yield convincing answers.^{151,223} Because of the possibility of common-source exposure, however, families of patients with acute acquired infection should be evaluated for subclinical infection.^{43,147}

Accidental self-inoculation with a needle contaminated with *Toxoplasma* has resulted in acquired infections in laboratory workers. Infections also have been ascribed to blood transfusions, stem cell transplantation, and organ transplantation.^{142,146,173}

Congenital Infection

Infection of the fetus occurs during maternal parasitemia, with subsequent infection of the placenta caused by tachyzoites.^{84,165,195,204} Placental infection represents an important intermediary step between maternal and fetal infection. A delay of 16 weeks between placental infection and subsequent infection of the fetus has been noted and is termed the prenatal incubation period.²⁰⁴ Congenital infection is thought to occur, with rare exception, only after primary maternal infection with *Toxoplasma*.^{61,62,204} The only two well-documented exceptions to this rule occurred in immunodeficient pregnant women.^{176,204} Maternal reinfection leading to congenital toxoplasmosis also has been reported very rarely.^{88,204} In a large series that carefully studied more than 800 women who had given birth to congenitally infected children, not a single congenital infection occurred in subsequent pregnancies.²⁰⁴ A general consensus is that only acute infection beginning during pregnancy can lead to congenital infection. Despite the existence of a few well-documented cases of biopsy-proven lymphadenopathic toxoplasmosis occurring 2 months before conception that resulted in congenitally infected infants, this pattern of occurrence also seems to be extremely rare.^{88,246} Congenital

toxoplasmosis has occurred in twins and triplets, with occasional discordance.^{45,204}

The incidence of congenital toxoplasmosis in a population is determined by the risk of a woman's experiencing primary infection while she is pregnant. This incidence depends on three factors: (1) the age-specific incidence of primary infection during the childbearing years, (2) the age distribution of pregnant women in the population, and (3) the fetal transmission rate in primary infection. A theoretical analysis by Frenkel^{83,204} that was based on these three factors, assuming a childbearing age group of 20 to 29 years and an overall fetal transmission rate of 40%, showed that maximal risk occurs when the age-specific incidence rate in a population is 3% to 5% per year, a rate that corresponds to a seropositivity prevalence of 50% to 80% in women of childbearing age. In such a population, the predicted incidence of congenital toxoplasmosis would be 4.4 to 4.6 per 1000 pregnancies. (A study from Brazil yielded prevalence and mother-to-infant transmission rates remarkably similar to these predictions.²⁴³) At higher age-specific incidences, rates of congenital toxoplasmosis would be lower because nearly all pregnant women already would be infected chronically. At lower incidences, rates also would be lower but because of less frequent acquisition of maternal infection.

Studies in the early 1970s revealed an incidence of congenital toxoplasmosis in the United States of approximately two per 1000 births.^{1,13,204} More recently, the incidence of congenital infection in the United States has been documented to be 0.08 per 1000 births (one in 12,000 births) by immunoglobulin M (IgM) screening of blood specimens collected on filter paper from newborns in Massachusetts and New Hampshire.¹⁰⁰ This is a conservative estimate because the methodology detects approximately 75% of infections. (A corrected figure would be one in 9000.) In this experience from Massachusetts, a case-control study involving 14 years of newborn screening for congenital toxoplasmosis found that birth of the mother outside the United States, particularly in Cambodia and Laos, was the strongest predictor, whereas live birth rate of the mother (≥ 3) and both extremes of educational level were also predictors of congenital infection.¹¹⁶ A global perspective is provided by a systematic review from the World Health Organization.²⁴⁰ Incidences of congenital toxoplasmosis in Europe ranged from 0.5 to 1.6 per 1000 and 0.6 to 3.4 per 1000 in Central and South America. The estimated global incidence was 190,000 cases per year.

PATHOLOGY

After intracellular multiplication at the site of entry occurs, tachyzoites are disseminated in blood and may invade all organs and tissues. The severity of infection probably is a function of strain virulence, host susceptibility, tissue tropism, the strain's ability to transit endothelial barriers, and the immune privilege of the eyes and central nervous system (CNS).^{97,98,150,195,204} Proliferation of tachyzoites results in death of the invaded cells and, eventually, small necrotic foci surrounded by intense cellular reaction. With recovery, cysts without an inflammatory response around them may persist in the brain, retinas, cochlea, bone marrow, lymph nodes, liver, spleen, and lungs, as well as in skeletal, heart, and smooth muscle.^{82–84}

In active infection of the CNS, *Toxoplasma*-filled cells are scattered throughout the gray matter, where they produce diffuse meningoencephalitis with miliary microglial nodules and foci of perivascular inflammation.⁴² Large lesions may mimic cerebral tumors. Areas of basal ganglial and periventricular inflammation may calcify in the fetus.^{67,193} Obstruction of the aqueduct of Sylvius or the foramen of Monro may result in hydrocephalus in congenital infection.¹¹⁰

The enlarged lymph nodes in acute acquired toxoplasmosis show characteristic pathologic changes that may warrant making a presumptive diagnosis.^{68,246} Such changes include reactive follicular hyperplasia, epithelioid histiocytes encroaching on and blurring the margins of germinal centers, and distention of subcapsular and trabecular sinuses by monocytoïd cells. Tachyzoites and cysts rarely are seen.⁶⁸

In the eye, active chorioretinitis begins in the retina with severe inflammation and necrosis and exudation into the vitreous. Single or multiple foci occur, and secondary involvement of the choroid is always present. Tachyzoites and cysts have been found in these lesions.^{24,204,208,209}

In immunocompromised hosts, widespread necrotizing lesions may be seen in the heart, muscle, brain, and other organs. These lesions, particularly those involving the CNS, have been found frequently with reactivation of toxoplasmosis in patients with acquired immunodeficiency syndrome (AIDS).¹⁴⁵

IMMUNOLOGY

Cell-mediated immune responses are the major immunologic mechanisms that prevent reactivation of *T. gondii* in a chronically infected normal host.^{37,53} Numerous effector mechanisms contribute to protection in murine models and human infection: CD8⁺ cytotoxic T lymphocytes, CD4⁺ T lymphocytes, monocyte oxidative mechanisms, production of interferon- γ by natural killer cells, and activation of macrophages by interferon- γ and tumor necrosis factor- α .^{91,102,125,127,224,233} Killing of the parasite within activated macrophages is associated with the release of interferon- γ and intracellular production of nitric oxide. Interleukin-2 and interleukin-12 enhance host resistance to *T. gondii*; interleukin-10 impairs the ability of macrophages to kill the parasite.⁹⁰

In murine models, evidence exists for genetic determination of host resistance to infection.^{26,25,150,161} Genetic and epigenetic factors at COL2A1, ABCA4, P2RX7, and ALOX12 influence susceptibility and clinical outcomes in human toxoplasmosis.^{112–114,260} Presence of the DQ3 allele also seems to be associated with toxoplasmic encephalitis in patients with AIDS and hydrocephalus in infants with congenital toxoplasmosis.^{25,26}

Successful immunization of mice²⁷ and sheep^{28,29} with *T. gondii* components and live tachyzoites of an "incomplete" strain raises the possibility of developing a human vaccine.^{117,162,252,254,266}

CLINICAL SYNDROMES

The disease in children may be considered in three categories: postnatally acquired, congenital, and ocular (which may be congenital or acquired).²⁰³ Clinically apparent infection in older children may have been acquired recently or caused by reactivation of latent congenital or postnatally acquired infection. Congenital and acquired infections usually are subclinical, but untreated or briefly treated congenital infection ultimately leads to serious sequelae in most cases.¹³²

Acute Acquired Toxoplasmosis

Acquired *Toxoplasma* infection is asymptomatic in most cases and frequently goes unrecognized because only 10% to 15% of infected individuals have clinical symptoms and signs. In certain outbreaks related to infection by oocysts, however, more than one-half of infected patients have been symptomatic.²³⁸ The most common findings are lymphadenopathy and fatigue without fever.¹⁵⁴ The nodes are discrete and may or may not be tender. They do not suppurate. The groups of nodes most commonly involved are the cervical, suboccipital, supraclavicular, axillary, and inguinal. The adenopathy may be localized or involve multiple areas, including the retroperitoneal and mesenteric nodes. Uncommonly, the lymphadenopathy is accompanied by fever, malaise, fatigue, sore throat, and myalgia, a picture that closely simulates that of infectious mononucleosis but without serologic evidence of acute Epstein-Barr virus or cytomegalovirus (CMV) infection. The differential diagnosis of the lymphadenopathy often includes lymphoma, necessitating excisional biopsy. Chorioretinitis may develop during acute acquired infection, but, in the United States, it does not occur commonly and is seldom vision threatening.^{151,180} For example, among mothers of congenitally infected infants in the National Collaborative Chicago-based Congenital Toxoplasmosis Study (NCCCTS), 10 of 130 mothers (7.7%) were found to have chorioretinal lesions (8 small, 2 medium-sized, all unilateral).¹⁸⁷ Ocular involvement is much more common and more severe in acquired disease in Brazil, a reflection of more virulent genotypes.^{2,128,227} The liver may be involved, and liver function test results may reflect hepatocellular damage. In individuals with normal immunologic function and no severe underlying disease in the United States and Europe, the infection usually is self-limited and seldom requires treatment.

In contrast, more severe and frequently fulminant infections are seen in patients receiving immunosuppressive therapy, in patients who

have disease of the bone marrow or reticuloendothelial system, in recipients of bone marrow or stem cell transplants, and in patients with AIDS.^{59,89,111,141,142,145,152,214,245} Encephalitis and rarely pneumonitis and myocarditis are the most important localized forms that may be encountered in immunocompromised patients. In toxoplasmic encephalitis, the predominant neurologic symptoms are headache, disorientation, and drowsiness. These symptoms may simulate aseptic meningitis or a mass lesion. In view of the various clinical manifestations of CNS involvement, it is important to consider toxoplasmosis whenever evidence of acute CNS disease is present in the setting of immunocompromise.

Epidemiologic studies have suggested a correlation between *Toxoplasma* infection and a variety of neurologic and psychiatric illnesses in adults, including schizophrenia, suicide rates in women, and Alzheimer disease.^{9,134,143,232} These intriguing findings require additional research before any conclusions can be reached.

Congenital Toxoplasmosis

Congenital infection usually is the result of an asymptomatic acute infection in the mother.^{23,78} In a small proportion of cases, spontaneous abortion, prematurity, or stillbirth may result. Congenital toxoplasmosis has a wide spectrum of clinical manifestations but is subclinical (i.e., not recognized in the usual neonatal examination) in approximately 70% of infected newborns. When it is clinically apparent, it may mimic other diseases of the newborn.

Involvement of the eyes and CNS involvement are the hallmarks of congenital *Toxoplasma* infection. The presence of chorioretinitis, intracranial calcifications, and hydrocephalus is referred to as the “classic triad” of congenital toxoplasmosis. Fever, hydrocephalus or microcephaly, hepatosplenomegaly, jaundice, convulsions, chorioretinitis (usually bilateral), cerebral calcifications, and cerebrospinal fluid (CSF) abnormalities (markedly increased protein concentration and mononuclear pleocytosis) are considered the classic features of severe congenital toxoplasmosis.^{67,172,204} These manifestations occurred commonly in an early series of patients from New York reported by Eichenwald⁷⁷ (Table 224.1). The case-fatality rate was 12%. In survivors in this series, sequelae included mental retardation in 86%; convulsions, spasticity, and palsies in almost 75%; and severely impaired vision in 60%.^{77,210} Other occasional findings included rash (maculopapular, petechial, or both), myocarditis, pneumonitis and respiratory distress, hearing defects, an erythroblastosis-like picture, thrombocytopenia, lymphocytosis, monocytosis, and nephrotic syndrome. *Toxoplasma* has been detected in the inner ear and mastoid, with the associated inflammation resulting in deafness.²¹⁹ Ascending flaccid paralysis with myelitis also has been reported.²⁰⁴ These signs now are known to be most typical of the severe form of the infection in the absence of treatment.

The risk for transmission to the fetus varies significantly with the trimester of gestation in which the mother becomes infected. The rates are approximately 15% in the first trimester, 30% in the second trimester, and 60% in the third trimester,^{48,61,62} rates that have been confirmed in data from the Systematic Review on Congenital Toxoplasmosis

(SYROCOT) study group in Europe.²³⁹ In contrast, the severity of clinical disease in congenitally infected infants is related inversely to the gestational age at the time of primary maternal infection (Table 224.2). In the original studies from France,⁶² disease that was clinically apparent at birth occurred in 8 of 11 (73%) infected live-born infants whose mothers had first trimester infection, in 19 of 68 (28%) with second trimester infection, and in only 8 of 76 (11%) with third trimester infection. Overall, 72% of live-born infected infants were asymptomatic. These findings were confirmed in subsequent studies from Paris¹⁰³ and the SYROCOT group.²³⁹

A later French prospective study of 210 congenitally infected infants born to mothers who were identified to have primary infection acquired during pregnancy (45% of whom were treated with spiramycin) revealed significant morbidity in 94 newborns.⁴⁸ Overall, 2 (0.9%) cases were fatal, 21 (10%) were severe, and 71 (34%) were mild; 116 (55%) cases were asymptomatic. These observations confirm that most congenital *Toxoplasma* infections are “subclinical” at birth. Obvious manifestations occur infrequently. Of the 116 infants in the same study with a normal routine newborn physical examination, however, 39 (34%) were found to have one or more abnormalities on closer scrutiny. Twenty-two of the 116 (19%) had abnormal CSF findings on lumbar puncture, 17 (15%) had chorioretinitis on indirect ophthalmoscopic examination, and 10 (9%) had intracranial calcifications on head radiographs or computed tomography (CT) scans. Guérina and colleagues¹⁰⁰ made remarkably similar observations in the congenitally infected newborns whom they identified in New England by heel-stick blood sampling.

Some infected children without overt disease as neonates may escape serious sequelae of the infection. However, a significant number (24% to 85%) will develop chorioretinitis, strabismus, blindness, hydrocephalus or microcephaly, cerebral calcifications, developmental delay, epilepsy, or deafness that will manifest months or years later. Three studies provide data that define the occurrence of these late sequelae.^{131,132,135}

In a study from Paris,¹³⁵ 26,402 apparently healthy infants were tested routinely for serologic evidence of *Toxoplasma* infection at 10 months of age. Of these infants, 51 (1.9 of 1000 births) had positive serologic results for *Toxoplasma*, indicative of congenital infection. None had been treated for *Toxoplasma* infection in infancy. Of the 51, five were found to have chorioretinal scars by ophthalmologic examination, and chorioretinal lesions had developed in another four children by the time they reached 4 years of age, the longest period of follow-up. Some children eventually lost functional vision in one eye. Three had intracranial calcifications.

Similarly, in a study from Holland in which a cohort of 1821 pregnant women were screened serologically, 12 congenitally infected infants were detected, and 11 of them were monitored for 20 years.^{131,132} Of the 11 children, five were treated as neonates for 1 month only, and six were not. Of the five treated infants, four had eye disease as neonates and one had parasites in CSF, which prompted therapy. Of the 11, nine (82%) had chorioretinal scars by the time they reached 20 years of age, and four of them, including two who were initially normal, had severe visual impairment or blindness in one eye. The onset of disease leading

to blindness occurred as late as 18 years of age. No neurologic or cognitive sequelae were observed.

The results of this Dutch study are similar to those previously reported by Wilson and associates²⁵⁹ from Alabama in a retrospective analysis of patients from the United States. During a mean follow-up period of 8.3 years, sequelae developed in 11 of 13 congenitally infected children (85%) who had no signs of disease on detailed examination in the newborn period. Sequelae included chorioretinal lesions in 11 children (85%), severe neurologic disability in one child (8%), and mental retardation in two children (15%). Sequelae first were noted at ages ranging from 1 month to 9 years. These 13 children were detected either as a result of routine screening of cord serum for IgM antibodies to *Toxoplasma*,¹ performed because acute *Toxoplasma* infection was diagnosed in the mother,²⁵⁹ or as a result of nonspecific findings in the neonatal period (two were small for gestational age, and one had transient borderline thrombocytopenia).

That treatment may decrease the frequency or severity of sequelae is suggested by the Alabama and Paris studies, in which chorioretinitis developed only in untreated infants between 10 months and 4 years old. Taken together, these data indicate that most congenitally infected children who receive no or brief treatment, including children with inapparent infection as neonates, experience untoward sequelae during childhood. Current treatment regimens—prolonged for at least 1 year and often initiated before birth—are associated with substantially less frequent and less severe sequelae (see section on treatment).

Congenital toxoplasmosis may mimic or coexist with infection by other organisms. It must be differentiated from other perinatal infections caused by CMV, herpes simplex virus (HSV), rubella virus, *Treponema pallidum* (syphilis), HIV-1, lymphocytic choriomeningitis (LCM) virus, Zika virus, and certain bacteria (e.g., *Listeria*). HSV, CMV, LCM, and Zika virus infections, syphilis, and rubella may cause chorioretinitis; CMV, LCM, HSV, and Zika virus and HIV-1 infections may cause encephalopathies associated with cerebral calcifications. Degenerative encephalopathies and storage diseases in older children also may resemble congenital toxoplasmosis.

Infants or preschool children with coexisting HIV infection and toxoplasmosis have been described.^{174,176} In at least six of these patients, HIV and *Toxoplasma* infections seem to have both been acquired in utero. Of these six patients, all but one had clinical evidence of CNS disease, and in most of these children, the CNS disease was associated with other findings common in congenital infection. These findings included hepatosplenomegaly, fever, and chorioretinitis and were evident at birth (one infant) or developed by the time the infant reached 4 months of age. Two of the other infants remained asymptomatic; one was treated for *Toxoplasma* infection, and the other was not treated. One additional infant who acquired HIV infection at 18 months of age from a blood transfusion died at 5 years of age of toxoplasmic encephalitis. The findings in this patient resembled those in adults with AIDS and toxoplasmic encephalitis.¹⁴⁵ The advent of highly active antiretroviral therapy (HAART) and the widespread use of trimethoprim-sulfamethoxazole for *Pneumocystis jirovecii* pneumonia prophylaxis (which has a prophylactic effect on *Toxoplasma*) have greatly decreased the frequency of clinical toxoplasmic encephalitis in children and adults with HIV infection.

Ocular Toxoplasmosis

In active congenital toxoplasmosis, the retinal lesions usually are bilateral.^{172,189} In older children, chorioretinitis may involve only one eye and may be the sole manifestation of congenital toxoplasmosis. Toxoplasmic chorioretinitis in Europe and the United States, even in older children and adults, usually is considered to be the result of congenital infection.¹⁸⁰ A report of 38 children diagnosed with symptomatic chorioretinitis between 2002 and 2004 in the United Kingdom confirmed that 58% of cases were the result of congenital infection.⁹³ In some studies, *Toxoplasma* infection has accounted for 5% of severe visual impairments in children.¹²⁶ Active lesions in the fundus appear as white or yellowish foci with elevated, edematous margins surrounded by a zone of hyperemia (Fig. 224.3). Cells and fibrinous exudate in the vitreous may obscure the fundus. Older lesions appear as glial scars, and in areas in which the retina has been destroyed, the choroid and sclera are visible. Around the depigmented areas, deposition of pigment from the destroyed retina is present. The position of the lesion may be macular, juxtapapillary, or peripheral; 58% of congenital lesions involve the macula.¹⁷²

Patients may experience loss of central vision (caused by a macular lesion), hazy vision (caused by accumulated exudate), or “floaters” (caused by reactivation of peripheral foci). Neonates or infants with toxoplasmic eye disease may have microphthalmos, small corneas, posterior cortical cataract, anisometropia, strabismus, and nystagmus.^{172,249} Strabismus and nystagmus in a child of any age should raise the possibility of congenital toxoplasmosis. The appearance of lesions in the fundus is not specific for toxoplasmosis. Similar lesions may occur with other less common granulomatous diseases in the eye, such as toxocariasis, congenital LCM and Zika virus infection, cat-scratch disease, and tuberculosis. Chorioretinitis may be recurrent, most commonly with reactivation at the margins of preexisting lesions.

LABORATORY DIAGNOSIS

Acute infection can be diagnosed by isolation of *T. gondii* from blood or body fluids; demonstration of tachyzoites in histologic sections of tissue or cytologic preparations of body fluids; characteristic lymph node histologic findings; demonstration of *Toxoplasma* cysts in the

placenta, fetus, or neonate; detection of the *Toxoplasma* genome by polymerase chain reaction (PCR) in body fluids; or characteristic serologic test results.^{21,164,177–179,199,205,257} Each of these methods is discussed, but serologic tests are emphasized because they are the most common and readily available methods to establish the diagnosis (Table 224.3).²⁵⁷

Serologic Methods

Measurements of IgG Antibody

The most useful tests for detection of IgG antibodies to *Toxoplasma* include the Sabin-Feldman dye test (the reference standard),^{140,215} indirect immunofluorescent antibody (IFA) test, agglutination tests, and enzyme-linked immunosorbent assay (ELISA). Titers in ELISA are expressed in different terms for different commercial kits, thus precluding a discussion of IgG ELISA titers in relation to the diagnosis of acute infection.^{65,251,257,267} In these tests, IgG antibodies appear within the first week of primary infection and reach peak titers (usually $\geq 1:500$) within 1 to 2 months; detectable titers usually persist for life. Although the dye test is the most reliable method, it is available in only a few reference laboratories. Immunoblot compares well with the dye test and may detect antibody slightly earlier than other methods, but it is also not widely available.^{124,138}

The IFA test and ELISA are the most widely available and, when properly performed, yield results similar to those obtained with the dye test; however, many laboratories use commercially available kits that are not consistently reliable. Because the performance of kits varies greatly, clinicians must be familiar with the variations if they are comparing results from different laboratories.¹³⁸ Some sera that contain antinuclear antibodies yield false-positive IFA test results.³ The direct agglutination tests that currently are available use formalin-fixed tachyzoites or antigen-coated latex particles, are simple to perform, and are accurate.^{228,257}

Initially after primary infection occurs, the avidity of IgG antibody for *T. gondii* antigen is low. Urea dissociates low-avidity antibodies, and a test has been developed that determines the percentage of antibodies that resist elution by 6 mol/L urea. This test is useful in the first 12

FIG. 224.3 Active and quiescent chorioretinitis caused by congenital toxoplasmosis in a 12-year-old patient. The active lesion (single arrow) is a satellite of an old chorioretinal scar (double arrows). (From Mets M, Holfels E, Boyer KM, et al. Eye manifestations of congenital toxoplasmosis. *Am J Ophthalmol*. 1996;122:309–24.)

TABLE 224.3 Guidelines for Interpretation of Serologic Tests for Toxoplasmosis

IgG	IgM	IgG Avidity	Interpretation
Positive	Negative	—	Remote infection, immune. IgG avidity testing is best used when both IgG and IgM are positive and timing of infection is crucial, as in pregnancy (see below). For evaluation of infection in the newborn, false-negative IgM results occur in approximately 25% of cases. If infection is suspected in this setting, further testing (dye test, IgM EIA, IgA EIA, IgE EIA/ISAGA, PCRs, ideally with paired maternal serology tests—see text) is necessary in a reference laboratory (<i>Toxoplasma</i> Serology Laboratory, PAMF Research Institute, 795 El Camino Real, Ames Building Palo Alto, CA, 94301; 650-853-4828).
Positive	Positive or equivocal	High	Infection within the past 18 mo but likely >12 wk ago. If pregnant and beyond first trimester, consider sending specimen to reference laboratory for dye test, repeat IgG avidity and IgM EIA, IgA EIA, IgE EIA/ISAGA, and AC/HS testing (see above).
Positive	Positive or equivocal	Low	Infection within the past 12 wk. Consider sending specimen to a reference laboratory (see above) to time infection more accurately (dye test, repeat IgG avidity and IgM EIA, IgA EIA, IgE EIA/ISAGA, and AC/HS) in the setting of pregnancy.
Equivocal	Negative	—	Indeterminate. Test a new specimen or consider a different assay (IFA or ELISA).
Equivocal	Equivocal	—	Indeterminate. Test a new specimen or consider a different assay (IFA or ELISA).
Equivocal	Positive	—	Acute infection or false-positive IgM result. Test a second specimen; if IgG becomes positive or remains equivocal, consider sending specimen to a reference laboratory to time infection more accurately (dye test, IgG avidity, IgM EIA, IgA EIA, IgE EIA/ISAGA, AC/HS—see text) in the setting of pregnancy.
Negative	Negative	—	No evidence of <i>Toxoplasma</i> infection; not immune.
Negative	Equivocal	—	Either false-positive IgM result or possible recent infection. Obtain a new specimen and retest. If infection is recent, IgM and IgG should become positive, with low IgG avidity. If repeated testing is still IgG negative and IgM equivocal, patient is likely uninfected. Consider IgM ISAGA.
Negative	Positive	—	Acute infection or false-positive IgM result. Repeat testing on new specimen. If the result is the same, it is likely a false-positive IgM result. Consider IgM ISAGA.

AC/HS, Differential agglutination test; EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay; IFA, immunofluorescence assay; Ig, immunoglobulin; ISAGA, immunosorbent agglutination assay; PCR, polymerase chain reaction.

weeks of gestation in that the presence of high-avidity antibodies excludes the acquisition of infection in the previous 3 months.^{30,182,257,265}

Other tests vary in their reliability. Indirect hemagglutination is widely available, but the results frequently are negative in newborns with congenital infection.²⁵⁷ This test should not be used for screening of pregnant women because detectable increases in titer are delayed compared with the increases detected by ELISA and by the dye, IFA, and agglutination tests. Meaningful interpretation of changes in titer on sequential sera requires that assays on each sample be performed in the same run by a reliable laboratory.²⁵⁷

Measurements of IgM Antibody

IgM antibodies are detected most commonly by the IgM IFA test, IgM immunosorbent agglutination assay (ISAGA), or IgM ELISA. IgM antibodies appear in the first week of primary infection and peak within 1 month.¹⁸⁵ Depending on the sensitivity of the method used, IgM antibodies may be demonstrable for 2 to 3 months or 1 year or longer. This prolonged presence of IgM leads to the most common diagnostic error in pregnant women—the assumption that a positive IgM result indicates fetal exposure, when the maternal infection may have occurred well before pregnancy began.⁶⁶ IgM ELISA and IgM ISAGA are much more sensitive than the IgM IFA test. Absence of IgM ELISA or IgM ISAGA antibodies in an immunologically normal older child (>1 year old) or adult essentially rules out a recently acquired infection.²⁵⁷ A negative IgM IFA test result is not as sensitive in ruling out recently acquired infection. Of sera that were negative with the IgM IFA test and obtained from adults who had acquired toxoplasmosis recently, 93% were strongly positive in IgM ELISA.¹⁸⁴ IgM IFA testing detects specific IgM antibody in only 25% of infants with proven congenital infection, whereas IgM ELISA detects antibody in approximately 75% of such cases.¹⁸⁴

The presence of rheumatoid factor or antinuclear antibodies may cause false-positive results in IgM IFA testing.³ The “double-sandwich” IgM ELISA avoids the false-positive results caused by the presence of rheumatoid factor, which the infant can produce in utero, and the false-negative results caused by competition from the high levels of maternal IgG antibody that occur in the IgM IFA test.^{183,257} In addition, the false-positive results in the IgM IFA test caused by antinuclear antibodies are not found in IgM ELISA.^{3,183}

ISAGAs are used widely in Europe. Similar to IgM ELISA, they capture IgM on a solid surface, detect specific IgM, and involve the addition of whole formalin-fixed organisms or *Toxoplasma* antigen-coated latex particles.^{64,202} These assays are available commercially and give results comparable to those of IgM ELISA, are simpler to perform, and do not require expensive equipment.

Measurements of IgA and IgE Antibodies

Demonstration of IgA and IgE antibodies in the fetus or newborn by ELISA and ISAGA seems to be at least comparable to the demonstration of IgM antibody in sensitivity for the diagnosis of congenital *Toxoplasma* infection.^{57,198,230,263} The IgA test also seems to be more sensitive than the IgM test for detection of acquired infection. Specificity remains an issue, however, so neither IgA/IgE ELISA nor IgA/IgE ISAGA has superseded the IgM test for diagnosis of acquired infection. IgA and IgE antibodies persist longer than IgM antibodies and may be useful in cases of subacute illness or when IgM titers are low.

Differential Agglutination

Acetone-fixed and formalin-fixed *T. gondii* tachyzoites may yield differing agglutination titers, depending on the acuity of the infection. The test based on this phenomenon is called the AC/HS differential agglutination test.⁵² In general, a disproportionately high agglutination titer with acetone-fixed organisms suggests acute infection; a disproportionately high titer with formalin-fixed organisms suggests chronic infection. Interpretative norms for this test have been established.⁵² This test, when it is combined with the dye test, IgM ELISA, IgA ELISA, IgE ELISA/ISAGA, and avidity studies, yields a “toxoplasmic serologic profile” that permits the most accurate evaluation of infection acuity in pregnant women,^{179,257,264} and often it can resolve any inconclusive or discrepant results obtained in a hospital or commercial laboratory.

Multiplexed Serologic Assays

A multiplex assay for anti-*Toxoplasma* IgG, IgM, and IgA antibodies uses microarray nanotechnology with plasmonic gold chips and near-infrared fluorescence enhancement.^{140,200} It has yielded high levels of sensitivity and specificity on small whole blood or serum samples when compared with the dye test (IgG) or double-sandwich ELISAs (IgM and IgA.) This newer technology may enable an accurate and cost-effective means of screening of mothers during gestation with single or small numbers of samples.

Point of Care Testing

The development of technology that would permit screening of maternal sera for IgG and IgM antibodies in an office setting by nontechnical personnel at the “point of care” has generated interest. One such system yielded 97% sensitivity and 96% specificity when random and selected specimens from obstetric practices in France were used.⁴¹ Because cost-benefit considerations must be taken into account in any systematic screening program, the application of this low-cost technology could make such programs more practical in the United States.

Nonserologic Methods

Nonserologic methods are now used less commonly to establish the diagnosis of *Toxoplasma* infection because they are not widely available, are labor intensive, and may require tissue specimens.

Isolation of the Organism

Isolation of *Toxoplasma* from blood or body fluids (e.g., CSF) establishes that the infection is acute. In the case of a neonate, isolation from the placenta or the infant's tissues is sufficient to diagnose congenital *Toxoplasma* infection. In 90% of placentas from which *T. gondii* is isolated, congenital infection has occurred.²⁰⁴ Sensitivity of placental detection of *Toxoplasma* by isolation for the diagnosis of congenital infection appears to vary, with reports from 25% to 67%, and depends on the trimester of acquisition of infection.^{80,206} Isolation of *Toxoplasma* from the tissues of older children or adults may reflect, however, only the presence of latent infection (cyst form). The organism may be isolated by inoculation of body fluids, leukocytes, or tissue specimens into the peritoneal cavities of mice or into tissue cultures. Specimens should be processed and inoculated immediately; however, tissue and blood may be stored at 4°C (39°F) overnight. Freezing and thawing or formalin treatment will kill the organism. Establishment of definitive diagnosis by isolation of *Toxoplasma* from tissues usually takes 4 to 6 weeks by mouse inoculation; tissue culture is less sensitive for recovery of *Toxoplasma*, but the results are available sooner.

Histology

Demonstration of tachyzoites, but not cysts, in tissue sections or smears of body fluids (e.g., CSF) establishes a diagnosis of acute infection. The organism may be difficult to see with routine stains. The peroxidase-antiperoxidase technique is exquisitely sensitive and has been used with a high degree of sensitivity and specificity to show the organism in biopsy specimens of the CNS in patients with AIDS.⁴² In older children and adults, the histopathologic changes in toxoplasmic lymphadenitis are sufficiently distinctive to enable pathologists to make a presumptive diagnosis of acute acquired toxoplasmosis (see section on pathology).^{68,246} Histologic demonstration of cysts establishes that a patient has *Toxoplasma* infection, but these findings are diagnostic of toxoplasmosis only in the placenta, fetus, or newborn.

Antigen-Specific Lymphocyte Transformation

Lymphocyte transformation in response to *Toxoplasma* antigens is a specific and sensitive indicator of previous *Toxoplasma* infection in adults and has been used successfully to diagnose congenital *Toxoplasma* infection in infants 2 months old or older.^{158,167,256} Lymphocyte transformation often is absent in the newborn period, however, particularly in more severely affected infants, because of specific immune tolerance.^{158,167}

Polymerase Chain Reaction

Amplification of the B1 gene of *T. gondii* DNA by PCR permits detection of the parasite in body fluids or tissues such as CSF, amniotic fluid,

and lymph nodes.^{38,99,104,191,212,213,219} Experience with the test in France, where PCR analysis of amniotic fluid was compared with the results of percutaneous umbilical blood sampling in 339 pregnant women, has shown that agreement of the two methods is almost 100% for the diagnosis of intrauterine infection.¹⁰³ In view of the considerably lower risk accompanying amniocentesis than with percutaneous umbilical blood sampling and the fact that amniocentesis potentially can be performed earlier in gestation, this diagnostic procedure has replaced umbilical sampling for prenatal diagnosis. An early prospective study in France showed, however, that only 48 (64%) of 75 amniotic fluid specimens from congenitally infected infants were positive by PCR analysis of a single sample obtained soon after maternal seroconversion. The test had a 100% positive predictive value, but a single negative assay did not rule out fetal infection.²¹³ However, a more recent report from the same institutions, using real-time PCR and the more repetitive REP-529 sequence as primer, for analysis of amniotic fluid of 261 acutely infected pregnant women yielded an overall sensitivity of 92% and a negative predictive value of 98%, with specificity and positive predictive values of 100%.²⁴⁸

A more recently developed nucleic acid amplification test, the loop-mediated isothermal amplification method (LAMP), uses the same general principle as conventional PCR but may offer a simpler and less expensive alternative if initial encouraging reports are confirmed prospectively.¹³⁶

Interferon- γ Release Assay

Interferon- γ release assays on whole blood have been approved for the diagnosis of latent tuberculosis infection. Two reports from France suggest that this same technique, using *T. gondii* instead of *Mycobacterium tuberculosis* antigens to stimulate white blood cells and then measuring the release of interferon- γ , has a sensitivity of 94% and a specificity of 98% for diagnosis of congenital toxoplasmosis.^{39,40}

Diagnosis in Specific Clinical Situations

Acute Acquired Toxoplasmosis

If IgM and IgG antibodies are not detectable, the diagnosis of acute *Toxoplasma* infection in an immunocompetent child virtually is excluded.^{255,257} The diagnosis of recently acquired infection is confirmed if seroconversion from a negative to a positive titer is noted or if a serial fourfold increase in titer to high levels is observed when sera drawn at 3-week intervals are run in parallel. A single high titer in any test is not diagnostic. A dye test or IFA titer of 1:500 or greater in the presence of a high IgM antibody titer probably is diagnostic of recent acute infection. Because IgM can remain positive for 18 months after acute infection, a serum IgG avidity test can be performed to time the infection more accurately. Low IgG avidity suggests that infection has occurred within the past 12 weeks, whereas high avidity suggests more remote infection.^{257,265} The absence of IgM antibodies in IgM ELISA or IgM ISAGA essentially excludes the diagnosis of acute infection. In contrast, the absence of IgM antibodies in the IgM IFA test does not mean that the infection is not acute; in one series, 25% of results in adults with acute infection were negative by the IgM IFA test.¹⁸⁴

Toxoplasma Infection in Immunodeficient Children

Serologic tests should be done to identify individuals at risk for acquiring toxoplasmosis, such as recipients of organ, stem cell, and bone marrow transplants. In candidates for transplantation, knowing the status of both donor and recipient is relevant. The available serologic tests may be inadequate to detect acute active infection in some immunodeficient patients because their antibody response may be abnormal, which is especially the case in stem cell and bone marrow transplant recipients.^{60,152} Experience in the Palo Alto, California, reference laboratory has revealed that acute infection may be present in patients with AIDS and in bone marrow transplant recipients without any demonstrable IgM antibody and in some immunocompromised patients who have little or no IgG antibody.¹⁴⁶ In patients with AIDS and active *Toxoplasma* infection, antibody titers in the modified direct agglutination test⁶⁵ may be elevated in the presence of low or undetectable titers in the dye or IFA test.¹⁵⁵ These and other immunodeficient patients can have progressive, lethal toxoplasmosis. In almost all cases, focal encephalitis, brain abscesses,

or both are the predominant findings; hepatic involvement, pneumonitis, and myocarditis may also be present. A high index of suspicion is necessary in these patients, and immunoperoxidase staining of appropriate biopsy specimens often is required to establish the diagnosis.⁴² Real-time PCR may be a valuable aid in these situations, although tissue immunoperoxidase staining remains the most reliable test.³⁸

Toxoplasma Infection in Pregnant Women

Toxoplasma infection acquired during pregnancy is associated with clinical signs (e.g., lymphadenopathy) in only 10% to 15% of patients. The fetus is at risk, however, for contracting the infection regardless of whether the mother is symptomatic. The best way to detect acute infection in a pregnant woman is a routine screening program in which serologic tests are performed periodically throughout pregnancy, as has been mandated in France since 1992.²⁵⁰ A suitable test for IgM antibody (IgM ELISA or IgM ISAGA) should be performed if a single random or clinically indicated serologic test result is positive at any titer. This is the common situation in countries such as the United States where screening is not mandated. If a suitable IgM antibody test is unavailable and the original serum contains IgG antibodies, the IgG antibody test should be repeated in 3 weeks, in parallel with the original serum, to determine whether the titer is stable or increasing.^{205,257} More recent experience with IgG avidity testing on a single maternal specimen suggests that this additional tool may be helpful in attempting to define maternal infection as acute (within the previous 12 weeks) or remote.^{30,54,182,199,205} The multiplex IgG, IgM, and IgA serologic screening test may be an accurate and economical newer approach to analyzing a single specimen during pregnancy.^{140,200}

If the IgM ELISA or IgM ISAGA result is negative and the IgG antibody titer is stable and less than 1:500, no further evaluation is necessary. Because IgG titers usually stabilize at high levels (e.g., the dye test or IFA titer $\geq 1:500$) at 6 to 8 weeks or longer after acquisition of the infection, if the dye test or IFA titer is less than 1:500 and stable (regardless of IgM antibody titer), infection was acquired at least 4 weeks and probably more than 8 weeks before the serum was obtained. In the United States, an asymptomatic woman commonly is evaluated for the first time more than 8 weeks after conception, however. If her dye test or IFA titer is 1:500 or greater, her IgM ELISA or IgM ISAGA result is negative, her IgG avidity is high, and no significant increase in titer in any test can be shown, her infection almost certainly was acquired before conception. In women with elevated IgM titers, low IgG avidity, or increasing IgG titers, infection possibly was acquired during pregnancy. In that case, a complete toxoplasmic serologic profile¹⁷⁹ in a reference serologic laboratory is recommended to settle the question.

Fetal Diagnosis

As noted earlier, severe congenital disease almost always is associated with primary maternal infection in the first or second trimester of pregnancy, but only 15% and 30%, respectively, of such maternal infections result in fetal infection.^{48,61,62} These rates in exposed fetuses may be reduced by half by maternal treatment with spiramycin.⁶² Identification of cases in which the fetus already is infected permits a parental decision to terminate the pregnancy or to treat the fetal infection more aggressively with pyrimethamine-sulfadiazine.

Studies by workers in Paris established an approach that allows definitive diagnosis and treatment of fetal infection in utero.^{50,63,103} After maternal seroconversion, these researchers initially sought to establish the diagnosis of fetal infection at 20 to 29 weeks of gestation by isolation of *Toxoplasma* from amniotic fluid or from fetal blood obtained by percutaneous umbilical blood sampling and use of the sensitive mouse inoculation method. Prenatal diagnosis was attempted in 746 pregnancies in which seroconversion occurred near the time of conception or before the 26th week of gestation. In 39 of these pregnancies, fetal infection was diagnosed in utero. *Toxoplasma* was isolated from fetal blood alone in 12 cases, from amniotic fluid alone in seven cases, and from both in 15 cases, for a total of 34. *Toxoplasma*-specific IgM antibodies were detected in fetal blood in only nine cases with the highly sensitive ISAGA, and no result was positive before 24 weeks of gestation. By follow-up examination until 3 months post partum or by examination of aborted fetal tissue, a total of 42 cases were proved to have been

infected. These researchers were able to detect 39 (93%) of 42 cases of fetal infection occurring before the 26th week of gestation; no false-positive diagnoses occurred.

These investigators subsequently extended their series and reported that a definitive diagnosis of infection was established in utero in 80 (90%) of 89 cases in which the fetus was infected.¹⁰⁴ However, the risks involved and technical expertise required in umbilical cord blood sampling have led to development of safer and less invasive, but equally sensitive, approaches to fetal diagnosis.

With the use of PCR to amplify the B1 gene of *Toxoplasma* in amniotic fluid obtained after 18 weeks of gestation, these same investigators were able to achieve sensitivity and specificity for the diagnosis of fetal infection that approached 100%.¹⁰³ In the most recent multicenter collaborative French study, in which a single specimen was prospectively studied in 261 pregnant women with acute toxoplasmosis, the specificity and positive predictive value remained 100%, with a sensitivity of 92% and a negative predictive value of 98%.²⁴⁸

These data demonstrated the value of specifically identifying exposed fetuses that truly are infected and are at risk for acquiring severe disease, thus enabling optimal maternal treatment. Negative results, conversely, allowed reassurance of parents and successful completion of pregnancies in which fetal infection had not occurred.

The current “state of the art” for management of maternal and fetal infection during pregnancy is described in the landmark study reported in 2013 from Lyon, France (the “Lyon Cohort”).^{195,250} This study included outcomes from 2576 women with gestational or periconceptional seroconversion who were studied between 1987 and 2008. Their protocols changed in 1992, when serologic screening was mandated in France, and again in 1995, when PCR analysis of amniotic fluid replaced umbilical cord venous sampling and mouse inoculation studies. All mothers with acute infection were treated with either spiramycin or alternating spiramycin and pyrimethamine-sulfadiazine/folinic acid until fetal involvement was evaluated. If fetal infection was documented, maternal pyrimethamine-sulfadiazine/folinic acid was given until delivery. If results of fetal studies were negative, spiramycin alone was given until delivery. After birth, all babies were treated with combinations of pyrimethamine and a sulfonamide for 12 months.

The risk of infection in exposed babies in the Lyon Cohort (before and after mandated screening in 1992) decreased from 59.4% to 46.6% ($P = .038$). The risk of clinical signs of infection (before and after diagnosis by PCR in 1995) decreased from 11.0% to 4.0% ($P = .012$). Of 207 infected children evaluated serially up to age 3 years, 46 (22.2%) had sequelae—five (2.4%) had hydrocephalus, 22 (10.6%) had intracranial calcifications, and 32 (15.4%) had chorioretinitis.²⁵⁰ By way of comparison, of 210 children with congenital toxoplasmosis referred to the NCCCTS in Chicago, 65 (31%) had hydrocephalus; these outcomes are a dramatic improvement.^{110,170} Because postnatal management in the two populations is very similar, the differences in outcome most likely are the result of the differences in obstetric and prenatal management in France.

Diagnosis of Congenital Toxoplasmosis After Birth

A thorough clinical and laboratory examination is necessary to evaluate fully the existence and extent of congenital toxoplasmosis in a newborn (Box 224.1). Demonstration of IgM, IgA, or IgE antibody in an infant's blood or CSF at any time is diagnostic of congenital infection if contamination by maternal blood can be reasonably excluded.²⁵⁷ Specimens obtained after the infant reaches 10 days of age are more reliable in this regard. If the much less sensitive IgM IFA test is used, the presence of antinuclear antibody and rheumatoid factor also must be excluded. As mentioned earlier, the detection rate in congenitally infected infants is 25% for the IgM IFA test and 75% for IgM ELISA and IgM ISAGA. Data are insufficient for predicting how often IgA and IgE antibodies are detected. IgM antibodies may be demonstrable in the first few days of life or may appear at variable times after birth. Investigators from France reported on their use of likelihood ratios of the various tests used to confirm congenital infection in 767 children born after acute maternal toxoplasmosis during pregnancy. The probability of a child's being infected was essentially 100% if the amniotic fluid was PCR positive and the IgM test result was positive in the newborn baby.²⁰¹ If both test

BOX 224.1 Evaluation of a Neonate When Serology of the Mother or Illness of the Neonate Indicates That a Diagnosis of Congenital Toxoplasmosis Is Suspected or Probable

In addition to a careful general examination, the infant is examined by the following:

Clinical Evaluation and Nonspecific Tests

Pediatric ophthalmologist

Pediatric neurologist

Brain CT (data suggest excellent agreement between CT and ultrasonography,¹²¹ which can be obtained more quickly and without the need for sedation)

Blood tests

Complete blood cell count with differential and platelet counts

Serum total IgM, IgG, IgA, and albumin

Serum alanine aminotransferase, total and direct bilirubin

CSF cell count, glucose, protein, and total IgG

Toxoplasma Gondii-Specific Tests

Newborn serum analyzed for antibody detected by Sabin-Feldman dye test,

IgM ISAGA, IgA EIA, IgE EIA/ISAGA (0.5 mL serum to *Toxoplasma* Serology Laboratory, PAMF Research Institute, 795 El Camino Real, Ames Building, Palo Alto, CA, 94301; 650-853-4828)

Newborn blood for inoculation into mice (1–2 mL clotted whole blood in red-topped tube to *Toxoplasma* Serology Laboratory)

Lumbar puncture: CSF dye test and IgM EIA (0.5 mL CSF to *Toxoplasma* Serology Laboratory); consider PCR (1 mL frozen CSF to *Toxoplasma* Serology Laboratory)

Sterile placental tissue (100 g in saline, from fetal side near insertion of cord, no formalin, to *Toxoplasma* Serology Laboratory for subinoculation)

Maternal serum analyzed for antibody detected by dye test, IgM EIA, IgA EIA, IgE EIA/ISAGA, and AC/HS

AC/HS, Differential agglutination test; CSF, cerebrospinal fluid; CT, computed tomography; EIA, enzyme immunoassay; Ig, immunoglobulin; ISAGA, immunosorbent agglutination assay; PCR, polymerase chain reaction.

Modified from McLeod R, Wisner J, Boyer K. Toxoplasmosis. In: Krugman S, Katz SL, Gershon AA, editors. *Infectious Diseases of Children*. St. Louis: Mosby, 1992:539.

results were negative, there was still a 10% probability of infection in their cohort.

If toxoplasmosis is suspected clinically but *Toxoplasma* is not isolated and IgM, IgA, or IgE antibodies are not detected, follow-up serologic testing is the only means of establishing the diagnosis. Maternally transmitted IgG antibodies may persist for 6 to 12 months or longer, depending on the original titer. The higher the original titer, the longer maternal antibody may be detectable in the infant. Synthesis of IgG *Toxoplasma* antibody usually can be shown by the third month of life if the infant is not treated; it may be delayed until the sixth or ninth month if the infant is treated. At the time that the infant begins to synthesize IgG antibody, infection may be documented by computing the specific “antibody load”—the ratio of specific serum antibody titer to the level of serum IgG in the infant.²⁰⁴ In the absence of infection, the antibody load decreases in the second or third month as the infant begins to produce IgG that does not contain specific *Toxoplasma* antibodies. In the presence of *Toxoplasma* infection, the infant produces specific antibodies, and the antibody load remains the same or increases. Most infected infants who are treated during the first year of life have a substantial increase in antibody after termination of therapy (serologic rebound).^{153,247} This phenomenon permits the diagnosis to be confirmed retrospectively in some uncertain cases.

Ocular Toxoplasmosis

Toxoplasma has been estimated to cause 35% of cases of chorioretinitis in the United States and Central and Western Europe.^{106,220,236} In these

regions, where clonal genotype II strains predominate, acquired toxoplasmosis usually is not accompanied by chorioretinitis.^{180,187} Most cases are thought to result from congenital infection that does not become clinically apparent until after reactivation. This event occurs most commonly in adolescence. In Central and South America, clonal genotype III organisms predominate, as well as other more virulent clones. In these regions, acquired toxoplasmosis may be severe and often is accompanied by acute vision-threatening chorioretinitis.^{2,18,31,227}

Although the presence of chorioretinitis should prompt a search for *Toxoplasma* infection, proof that *Toxoplasma* caused the eye disease may be lacking. The titer of antibody in serum often does not correlate with the presence of active lesions in the fundus. Low titers of IgG antibody are the usual finding in patients with reactivation *Toxoplasma* chorioretinitis. IgM antibodies generally are absent. *Toxoplasma* probably is excluded as a cause of chorioretinitis if the results of serologic tests are negative in undiluted serum. If the retinal lesions are characteristic and serologic test results are positive, the diagnosis is probable. If the retinal lesions are atypical and the serologic test results are positive, the diagnosis of *Toxoplasma* chorioretinitis is less certain because of the increasing prevalence of *Toxoplasma* antibodies with age in the normal population. Finding *Toxoplasma* antibodies in the child's mother supports the possibility of congenital infection, as does detection of intracranial calcification on CT scan of the patient. Demonstration of local antibody production or *Toxoplasma* DNA by PCR in aqueous humor obtained by paracentesis of the anterior chamber can be used to establish the diagnosis of *Toxoplasma* chorioretinitis in equivocal cases, but neither test is fully sensitive.^{19,204,257} Thus, the risk of this procedure when vision is threatened must be weighed against the relatively low risk of a course of empiric treatment.

TREATMENT

The need for therapy and the duration of therapy are determined by the nature and severity of the clinical illness and by the immune status of the infected patient. Antibody titers are not useful indicators of therapeutic response, and an increasing antibody titer soon after discontinuation of therapy (serologic rebound) is not an indication of therapeutic failure. Specific therapy acts primarily against the tachyzoite form; the drugs currently available do not eradicate the encysted form containing bradyzoites. Close, longitudinal follow-up and supportive interventions are crucial contributors to therapeutic success.

Therapeutic Agents

The therapeutic agents used, their dosages, and indications for their use in the management of toxoplasmosis are included in Table 224.4 and discussed next.

Spiramycin

Spiramycin is a macrolide that has been used extensively in Europe (but also in the United States) to reduce transmission of infection from an acutely infected mother to the fetus in utero.⁴⁵ It is typically prescribed initially if there is documentation of seroconversion and is continued (1) until delivery if amniotic fluid studies are negative or (2) until initiation of pyrimethamine-sulfadiazine/folinic acid if fetal infection is documented.^{195,250} It is concentrated in the placenta and is reported to reduce transmission by 50% to 60%. It reduces the ability to isolate the organism from the placentas of definitively infected newborns from 95% to 80%.⁴⁷ Spiramycin is less effective than pyrimethamine-sulfadiazine in the treatment of congenital infection and toxoplasmic

TABLE 224.4 Treatment of Toxoplasmosis

Disease	Medication	Dosage	Length of Therapy
Acute acquired—generally not treated unless severe or persistent symptoms, vital organ damage, or host is immunosuppressed ^a	Pyrimethamine plus Sulfadiazine plus Folinic acid	2 mg/kg/day for 2 days, then 1 mg/kg/day 75–100 mg/kg/day divided twice daily (maximum 4 g/day); consider the lower dose in children >20 kg (see text) 5–20 mg 3 times weekly; use higher doses if marrow suppression	4–6 wk or 2 wk after symptoms resolve for normal host; 4–6 wk beyond resolution for immunosuppressed hosts. In AIDS, treat until CD4 ⁺ count >200
Ocular, older child	Pyrimethamine plus Sulfadiazine plus Folinic acid plus Prednisone	2 mg/kg/day for 2 days, then 1 mg/kg/day (maximum 50 mg/day) 75–100 mg/kg/day divided twice daily (maximum 4 g/day); consider the lower dose in children >20 kg (see text) 5–20 mg 3 times weekly 1 mg/kg/day divided twice daily	4–6 wk or 2 wk after symptoms resolve Prednisone should be continued until resolution of sight-threatening active chorioretinitis
Congenital	Pyrimethamine plus Sulfadiazine plus Folinic acid plus Prednisone	2 mg/kg per day for 2 days, then 1 mg/kg/day for 6 mo, then 3 times weekly (M-W-F) for 6 mo 100 mg/kg per day divided twice daily 5–10 mg 3 times weekly 1 mg/kg/day divided twice daily	1 y Until resolution of elevated CSF protein level or sight-threatening active chorioretinitis
Pregnant women—acute infection first 21 wk of gestation	Spiramycin	3 g/day divided twice daily without food	Until fetal infection documented or excluded at 21 wk of gestation; if fetus infected, change to pyrimethamine plus sulfadiazine plus folinic acid until delivery
Pregnant women—fetal infection confirmed (amniotic fluid PCR positive)	Pyrimethamine plus Sulfadiazine plus Folinic acid	100 mg/day divided twice daily for 2 days, then 50 mg/day 3 g/day divided twice daily 5–20 mg/day	Until delivery

AIDS, Acquired immunodeficiency syndrome; CSF, cerebrospinal fluid; PCR, polymerase chain reaction.

encephalitis.^{46,47,61,221,222} Toxoplasmic encephalitis has developed in patients receiving spiramycin and has been treated effectively with pyrimethamine-sulfadiazine. Toxicities include allergic manifestations, gastrointestinal intolerance, and paresthesias.

Spiramycin apparently does not treat manifestations of *T. gondii* infection in the fetus in utero.^{47,61,104,221} It formerly was used in alternate-month regimens with pyrimethamine and sulfadiazine for postnatal treatment of congenital toxoplasmosis in France.²⁰⁴ Spiramycin is not approved by the US Food and Drug Administration but may be obtained with compassionate clearance by calling 301-796-1400. The manufacturer (Aventis-Pasteur, 800-633-1610) provides the drug after the diagnosis has been documented and Food and Drug Administration forms have been completed.

Pyrimethamine

Pyrimethamine is a folate antagonist that has been shown to be effective against *T. gondii* in vitro,^{169,166} in animal models,⁸⁶ and in human infections.^{49,51,86,148,169,264} It is considered the drug of choice for *T. gondii* infection. When this drug is used in conjunction with sulfadiazine, based on their inhibition of sequential steps in folate metabolism, synergy can be shown. The pharmacokinetics of pyrimethamine has been studied in infants and adults.^{169,253} Pyrimethamine is metabolized in the liver. The pharmacokinetics is not altered by renal insufficiency but is affected by concomitantly administered drugs (e.g., phenobarbital). Pyrimethamine toxicities include reversible marrow suppression (most commonly) and allergy. Aplastic anemia, hepatotoxicity, and various allergic manifestations (including Stevens-Johnson syndrome) also have been listed as toxicities of this medication. Pyrimethamine always should be administered in conjunction with leucovorin (i.e., folinic acid) because human cells can use folinic acid for synthesis of nucleic acids, but *T. gondii* cannot.¹⁶⁹

Leucovorin

Leucovorin (folinic acid) always is administered during treatment with pyrimethamine. Folinic acid has a protective effect for human cells that folic acid does not. (Confusion of the two in prescribed regimens can be harmful.) Increased doses of leucovorin are used in the event of marrow suppression. Because of the long half-life of pyrimethamine (60 hours in infants), continuation of leucovorin therapy for 1 week after discontinuation of a course of pyrimethamine is recommended.

Sulfadiazine

The three sulfonamides sulfadiazine, sulfamerazine, and sulfamethazine (known as triple sulfa when used in combination) are the three most active of the sulfonamides against *T. gondii* and are synergistic with pyrimethamine in their activity against *T. gondii*. Of the three drugs, however, only sulfadiazine is available in the United States. All other sulfonamides are less active in vitro.¹⁶⁶ The sulfonamides are excreted by the kidney, and the dosage must be adjusted for patients with renal insufficiency. Nephrolithiasis can occur in older children and adults, in whom urinary acidification is more effective, and fluid requirements are lower on a weight basis than in infancy. The risk for development of stones in these groups can be reduced by aggressive fluid supplementation (1–2 L above maintenance) and urine alkalinization.³⁴ In older children who weigh more than 20 kg, a dose of 75 mg/kg per day (rather than the conventional 100 mg/kg per day) should be considered because this dose more closely approximates the calculated adult dose based on body surface area. Other sulfonamide toxicities include allergy (including Stevens-Johnson and DRESS [drug reaction with eosinophilia and systemic symptoms] syndromes), marrow suppression, and hepatotoxicity.¹⁶³ Sulfonamide pharmacokinetics have been studied in infants.²⁰⁴

Clindamycin

Although the effect of clindamycin is delayed, it does have an effect in vitro against *T. gondii* with prolonged time in culture.¹⁹⁶ The drug also has been shown to be effective in murine models. Clindamycin has been found to be comparable in efficacy to sulfadiazine for the treatment of toxoplasmic encephalitis in adult patients with AIDS when it is used in a combined high-dose regimen with pyrimethamine.^{51,148}

Other Antimicrobial Agents

Because the activity of sulfamethoxazole is less than that of sulfadiazine, trimethoprim-sulfamethoxazole has been considered less effective and is not used for treatment of congenital toxoplasmosis. Many investigators have used this combination successfully, however, to treat toxoplasmic encephalitis in adults with AIDS.²⁴¹ Prophylactic doses of trimethoprim-sulfamethoxazole, as used to prevent *P. jiroveci* pneumonia, also seem to prevent episodes of reactivated toxoplasmosis.^{32,79} A randomized controlled trial showed that trimethoprim-sulfamethoxazole is as effective as pyrimethamine-sulfadiazine in the treatment of isolated ocular toxoplasmosis in young adults.²²⁹ In vision-threatening disease, however, pyrimethamine-sulfadiazine is preferred.

Pyrimethamine combined with sulfadoxine, despite having lower in vitro activity than pyrimethamine-sulfadiazine, is widely used in Europe to treat both reactivated and congenital infection.^{15,166,194,195,237,250} Sulfadoxine has an even longer half-life than pyrimethamine, thus enabling it to be used in weekly or 10-day dosing regimens. It has the added advantage of availability in suspension form, a convenience in prescribing for infants and children. Its long half-life is a disadvantage, however, in the event of sulfonamide hypersensitivity. Numerous other antimicrobial agents have been shown to be effective in vitro or in animal models against either tachyzoites or encysted bradyzoites,^{4–8,105,106} but their role, if any, in the treatment of human disease remains to be defined. Atovaquone (5-hydroxynaphthoquinone) was effective against bradyzoites within cysts in vitro.¹⁰⁸ However, 13% of patients with AIDS had progression of toxoplasmic encephalitis while being treated with this antimicrobial agent,²⁴² so it does not appear to have the desired effect in vivo. Other antimicrobial agents with an effect on *T. gondii* tachyzoites in vitro or in vivo include cycloguanil¹⁰⁵; artemisinin¹⁰⁵; rifabutin⁸; and the macrolides clarithromycin, azithromycin, and roxithromycin.^{4,6,7} Isolated reports of clinical use of some of these agents, most typically when standard agents are not available or not tolerated, have appeared in the literature with mixed results. In patients with vision-threatening recurrent chorioretinitis, long-term prophylaxis with azithromycin has been safe and effective in some cases (R. McLeod, personal communication).

The major unsolved therapeutic problem in toxoplasmosis is the lack of a safe agent that could eliminate encysted bradyzoites, a therapeutic approach which would be analogous to isoniazid treatment of latent tuberculosis infection. Investigational agents that target calcium-dependent protein kinase 1 and the cytochrome bc₁ complex in encysted bradyzoites have recently shown promise in model systems.^{171,244}

Therapy in Specific Clinical Settings

Acquired Toxoplasmosis

Most immunologically normal patients with the lymphadenopathic form of toxoplasmosis do not require specific treatment. Indications for treatment in these cases are the presence of severe and persistent symptoms and damage to vital organs. Because of the high incidence of severe morbidity and mortality in immunocompromised patients, toxoplasmosis should be treated in this population. Most immunocompromised patients in whom the diagnosis is established ante mortem improve when specific therapy is administered. The major problem lies in establishing the diagnosis early enough to institute treatment.

The optimal duration of specific therapy for toxoplasmosis is unknown. Patients who seem to be immunologically normal but who have severe and persistent symptoms or damage to vital organs should receive specific therapy for 2 to 6 weeks, provided symptoms resolve. In immunocompromised patients, therapy should continue at least 4 to 6 weeks beyond complete resolution of all signs and symptoms of active disease. Careful follow-up of these patients is imperative because relapses may occur and require prompt reinstitution of therapy. In patients with AIDS in whom toxoplasmosis develops, suppressive therapy with pyrimethamine-sulfadiazine, pyrimethamine-clindamycin, or trimethoprim-sulfamethoxazole should be continued for life or until immune reconstitution has been sustained for at least 6 months.²²⁵

Treatment of Pregnant Women

Treatment of an acutely infected woman during pregnancy may prevent transmission of the infection to her fetus. The rationale for such treatment

is derived from the observation that the incubation period between the onset of maternal infection and acquisition of infection in the fetus may be significant. Data from France,^{61,62} where women with seroconversion were treated with spiramycin, and from Austria^{10,11} and Germany,¹³³ where women were treated with pyrimethamine and sulfonamides, indicate that the incidence of congenital infection in the children of mothers treated during gestation is at least 50% less than that in the children of untreated mothers. None of these studies was controlled rigidly. A meta-analysis including 20 cohorts with 1721 infected mothers and 506 infected children suggested that a reduction in the incidence of transmission (odds ratio: 0.48; 95% confidence interval: 0.28–0.80) was achieved if therapy was started within 3 weeks of maternal seroconversion.²³⁹ These results, combined with the numerous women studied by the groups from France, strongly suggest that intrauterine treatment does reduce the incidence of transmission of maternal infection to the fetus.^{62,195,250} A more recent report of an observational cohort included in the analysis from the European Multicentre Study on Congenital Toxoplasmosis (EMSCOT) showed a significant reduction not only in transmission but also in serious neurologic sequelae for children with congenital toxoplasmosis who were treated prenatally, with the most significant impact for those women who seroconverted in the first 10 weeks of gestation.⁴⁴ The studies from Lyon, mentioned earlier, also revealed a marked reduction in clinically significant manifestations of congenital infection in babies treated prenatally and postnatally with combinations of pyrimethamine and sulfonamides (sulfadiazine and sulfadoxine).²⁵⁰ Long-term follow-up of congenitally infected young adults who were treated antenatally and postnatally in the Lyon cohort showed remarkably normal quality of life and visual function.¹⁹⁴ An additional report from a different center in France similarly found minimal disability (74% asymptomatic, 26% with chorioretinitis, and one child with serious neurologic involvement) in 107 children treated both prenatally and postnatally.¹⁶

Postnatal treatment of congenital infection. Data regarding the efficacy of postnatal treatment of infants with congenital *Toxoplasma* infection are becoming available.^{94,160} However, as discussed previously, the improved outcomes reported from several centers in France generally include prenatal treatment as well as postnatal therapy. Nevertheless, uncontrolled studies in humans and controlled studies in experimental animals²⁰⁴ have indicated beneficial effects of postnatal treatment on the development of sequelae in both symptomatic and asymptomatic infants with congenital *Toxoplasma* infection. The controlled NCCCTS has been in progress since 1981.^{153,159} This study seeks to define optimal postnatal therapeutic regimens. Physicians treating patients in the United States with congenital *Toxoplasma* infection who are younger than 2.5 months of age may wish to contact this multidisciplinary group about potential enrollment of their patients in that study (773-834-4152).

Outcomes to date from the NCCCTS have been substantially better for most but not all infants treated from the neonatal period for 12 months with pyrimethamine-sulfadiazine and leucovorin than for historical controls receiving no or short-course therapy.^{153,159} Signs of active infection resolve within weeks of initiation of treatment. In many children, the appearance of brain CT scans has improved remarkably. Cerebral calcifications have diminished in size or resolved in most such treated children.¹⁹³ In conjunction with this improvement in brain CT scans, cognitive function has been in the normal range (including the high normal range) for 69% of treated children.^{211,234} Overall, 18 (27%) of 66 children in the NCCCTS have intelligence quotient (IQ) results lower than 70 compared with 86 (85%) of 101 untreated or briefly treated children in the reported literature (see Table 224.1).^{77,159}

No significant diminution in cognitive function occurs over time, and most treated children function well in regular school classrooms. Although the number of children compared is limited, for a small subset of these children measures of cognitive function seem to be less than those for their siblings. No sensorineural hearing loss has been ascribable to congenital toxoplasmosis in treated children.^{153,157,159} Despite the much improved neurologic outlook for most of these children, a subset of children with significant irreversible neurologic damage already present in the perinatal period has manifested profound developmental delay, motor impairment, and seizures. For the most part, these were children with hydrocephalus, high CSF protein concentration, minimal improvement

in brain CT scans after shunting, and often substantial delays in shunt placement or needed revision for shunt failure or other intercurrent medical problems.^{110,234} This experience emphasizes the importance of recognizing hydrocephalus and managing it aggressively.

Although treatment during the first year of life arrests all signs of active disease, results in normal cognitive and motor outcomes for most children, and may result in resolution of seizures without recurrence for some treated children, the drugs currently available do not eradicate all cysts containing bradyzoites. In most children, serologic titers of *T. gondii*-specific antibodies rebound in the 3 to 4 months after treatment is discontinued.^{153,159,247}

To date, new retinal lesions have occurred in 17 of 58 children in the NCCCTS during 3 to 10 years' follow-up after the 1-year course of treatment.¹⁵⁹ These active lesions have responded to brief courses of treatment with pyrimethamine, sulfadiazine, and leucovorin without subsequent loss of visual acuity. Although follow-up durations are shorter, this result contrasts with the almost uniform eventual development of retinal lesions in studies of untreated or briefly treated children in the United States and Europe.^{45,77,131,132,247} We recommend that infected children undergo retinal examination each month for 3 months after discontinuing treatment around their first birthday, then every 3 months until they are old enough to describe visual symptoms accurately, and then every 6 months. In addition, an ophthalmologic evaluation should be performed promptly for any acute visual signs or symptoms (e.g., "floaters," acuity changes) that may be related to recrudescence of congenital ocular toxoplasmosis.¹⁷²

Sequential fetal and postnatal treatment. Several studies^{44,76,87,96} have described outcomes in patients treated in utero with continuing treatment during the first year of life. As noted earlier, however, some pregnancies in France in which fetuses had obvious manifestations on ultrasound examination and most pregnancies with definite first trimester fetal infection were terminated. For example, in the study from Toulouse,^{16,17} of 676 women with seroconversion, 10 (1.5%) chose termination based on these criteria. However, of the 107 infected babies in the same cohort who were tested, treated, and followed for an average of 9 years, 79 (74%) were asymptomatic and free of eye disease. Similarly, in the analysis of data from the Lyon cohort,²⁵⁰ of 207 treated babies followed up to age 3 years, 80% were free of *Toxoplasma*-related symptoms.

These findings contrast starkly with the presence of retinal or neurologic involvement in 50% of asymptomatic newborns detected in the newborn period by serologic screening in Massachusetts¹⁰⁰ and in 75% of children whose pediatricians referred them to our NCCCTS for treatment in the postnatal period.^{159,170} A prospective study (as part of the NCCCTS) is under way to compare outcomes in infants identified by obstetricians, as detected prenatally and treated in utero, with those identified by pediatricians after birth and then referred and treated postnatally.

Coexistent HIV Infection

Active toxoplasmosis with coexistent HIV infection in children is increasingly rare since the advent of HAART and effective prevention of vertical HIV transmission.^{75,175,190} Most children described with toxoplasmosis and HIV infection in the past have had congenital toxoplasmosis and have been symptomatic. For such children, concomitant therapy with HAART and pyrimethamine-sulfadiazine/folinic acid is recommended in the doses described in Table 224.4.²²⁵ HIV-infected adult and adolescent patients receiving secondary prophylaxis with trimethoprim-sulfamethoxazole (i.e., long-term maintenance therapy) after toxoplasmic encephalitis are at low risk for recurrence when they have successfully completed initial therapy, remain asymptomatic with regard to signs and symptoms of toxoplasmic encephalitis, and have sustained increases in CD4⁺ T lymphocyte counts of more than 200 cells/ μ L after effective HAART.²²⁵

Although the numbers of patients with toxoplasmic encephalitis who have been evaluated remain limited and occasional recurrences have been reported, on the basis of these observations and inference from more extensive cumulative data indicating the safety of discontinuing secondary prophylaxis for other opportunistic infections during advanced HIV disease, discontinuation of long-term maintenance therapy among such patients is a reasonable consideration.²²⁵ (Also see

<http://aidsinfo.nih.gov/guidelines/> for the latest Department of Health and Human Services recommendations regarding treatment and prophylaxis of toxoplasmosis in AIDS.) The highest risk for relapse seems to occur within the first 6 months of discontinuing secondary prophylaxis. Many specialists would obtain a magnetic resonance image of the brain as part of their evaluation to determine whether it is appropriate to discontinue therapy. Zidovudine is known to antagonize the toxoplasma effect of pyrimethamine and its in vitro synergy with sulfonamide. Whether this effect occurs in vivo is unknown.¹³⁷

Recurrent Ocular Toxoplasmosis

Because currently available therapies do not eradicate bradyzoites, recurrences of toxoplasmic chorioretinitis are a lifelong threat for children with congenital infection. Prompt initiation of specific treatment in reactivated ocular toxoplasmosis is mandatory to preserve vision. Inflammatory reactions in the vitreous are a frequent clinical finding in patients with reactivation, and in such cases coadministration of corticosteroids in addition to specific anti-*Toxoplasma* therapy is recommended strongly.¹⁷² The use of corticosteroids also is recommended for cases of vision-threatening retinochoroiditis involving the macula, maculopapillary bundle, or optic nerve. The initial daily dosage of prednisone is 1 mg/kg orally to a maximum of 75 mg in 24 hours. The equivalent dosage of another corticosteroid may be given. The dosage of corticosteroid may be reduced gradually when the lesion appears to be well demarcated and pigmentation has begun. Some physicians have administered systemic or intraocular clindamycin to treat patients in whom the use of corticosteroids and pyrimethamine plus sulfadiazine has failed²³⁵; the efficacy of this approach has not been proved in humans. Choroidal neovascular membranes and subretinal hemorrhages resulting from reactivated toxoplasmic chorioretinitis have been treated successfully with intravitreal anti-vascular endothelial growth factor monoclonal antibody preparations.¹⁴

PREVENTION

The entire issue of congenital infection may be avoided by preventing primary *Toxoplasma* infection during pregnancy.^{81,156,258,265} This approach has come to be known as primary prophylaxis. The responsibility of all physicians caring for pregnant women at risk is to inform them of specific hygienic measures (Box 224.2) for avoiding *Toxoplasma* infection. Similar measures are useful for prevention of acquired infection in other settings as well. The effectiveness of a 10-minute education program, offered as part of prenatal care, to reduce the risk of acquiring *Toxoplasma* infection by modifying the behavior of pregnant women with regard to cats, food, and personal hygiene has been shown.³³ Internet resources that describe methods to prevent toxoplasmosis in pregnant women are available from the March of Dimes (www.marchofdimes.org/pregnancy.toxoplasmosis.aspx) and from the Centers for Disease Control and Prevention (www.cdc.gov/parasites/toxoplasmosis/resources/ToxoWomen_2.2003.pdf).

When primary maternal infection has occurred, several problems are inherent in the secondary prevention of congenital toxoplasmosis by pregnancy termination or by treatment of the pregnant woman.³⁵ Because 80% to 90% of women with primary *Toxoplasma* infection are asymptomatic, most primary infections are overlooked, unless sequential serologic testing is performed routinely in pregnant women. The cost effectiveness of routine screening in the prevention of congenital toxoplasmosis is abundantly clear in some European countries where screening is mandated by law.^{61,62} In countries with a significantly lower incidence, cost efficacy is more difficult to prove.^{92,95,207} An analysis of the cost of a universal screening program for pregnant women in the United States modeled after the French approach suggests cost savings for the US population even with current levels of congenital infection of approximately one case per 10,000 live births.^{100,129,207,231} In the absence of national guidelines, physicians may choose to screen patients on an individual basis.²⁵⁸ If screening is undertaken, a reliable serologic test for IgG antibodies (see section on laboratory diagnosis) should be performed before conception occurs or as soon as possible thereafter and then repeated every 2 to 3 months until the time of delivery. Serologic test results that suggest the acquisition of primary infection during

BOX 224.2 Prevention of Toxoplasma Infection

Prevention of Acquired Infection (Primary Prevention)

Cook meat to medium (66°C [150°F]), smoke it, or cure it in brine.

Wash fruits and vegetables before consumption.

Avoid touching mucous membranes of the mouth and eyes while handling uncooked meat or unwashed fruits or vegetables.

Wash hands and kitchen surfaces thoroughly after contact with raw meat or unwashed fruits or vegetables.

Prevent access of flies, cockroaches, and other coprophagous insects to fruits and vegetables.

Avoid contact with materials that potentially are contaminated with cat feces, such as cat litter boxes, or wear gloves when handling such materials and when gardening.

Disinfect cat litter boxes for 5 minutes with nearly boiling water.

Prevention of Congenital Infection (Secondary Prevention)

Identify women at risk by serologic testing.

Treatment of acute maternal infection with spiramycin during pregnancy results in an approximately 50% reduction in the incidence of infection in infants.

Maternal treatment with pyrimethamine, sulfadiazine, and leucovorin, when fetal infection is documented by amniotic fluid PCR, significantly improves clinical outcome.

Therapeutic abortion may prevent birth of a severely affected infant—consider for PCR-proven fetal infection in the first two trimesters with abnormalities documented by ultrasound or MRI.

MRI, Magnetic resonance imaging; PCR, polymerase chain reaction.

Modified from Remington JS, Wilson CB. Toxoplasmosis. In: Kass EH, Platt R, editors.

pregnancy (IgG seroconversion and/or IgM or IgA antibodies) should be confirmed by a reference laboratory. Decisions about treatment or therapeutic abortion should be based on a consideration of whether the fetus is infected or affected, as determined by amniocentesis and ultrasonography.

Acknowledgments

We acknowledge Drs. Jack Remington, Rima McLeod, and James McAuley as contributors to work in the previous edition from which this chapter was constructed.

Pneumocystis pneumonia (PCP) is a life-threatening pneumonia that occurs in immunocompromised infants, children, and adults. Even with modern medical management, mortality is significant. Although the organism has been identified in a variety of tissues, the pathologic process is generally limited to the lungs. Infection in the normal child is common, with most children infected by 2 years of age with a mild or asymptomatic respiratory tract infection. Chemoprophylaxis is highly effective in preventing PCP in at-risk patients.

ORGANISM

Pneumocystis was originally identified in 1909 by Chagas, who believed it was a form of *Trypanosoma cruzi*.⁹ It is now known to be a unique and ubiquitous pathogen of mammals. The first description of *Pneumocystis* infecting a human was reported in 1942.⁷⁶ The taxonomic placement of *Pneumocystis* has been difficult and has varied over time. The organism has features of both protozoa and fungi. Protozoan features include morphology with three distinct forms, termed cyst, sporozoite, and trophozoite; sensitivity to antimicrobial agents with activity against protozoal organisms; and resistance to most antifungal drugs. Fungal features include the structure of the cyst wall, which contains chitin and β -1,3-glucan, and its genetic structure is more typical of that of fungi.^{20,21}

Because *Pneumocystis* cannot be maintained in culture, definitive knowledge of its life cycle is limited. The thick-walled cyst is 5 to 8 μ m in diameter and contains up to 8- μ m sporozoites (or intracystic bodies), which on leaving the cyst become trophozoites (or tropic forms) varying in size from 1 to 4 μ m (Fig. 225.1). There is some evidence for a sexual cycle in *Pneumocystis* based largely on the presence of homologs of genes involved in sexual cycles in fungi.

Pneumocystis strains or species have the remarkable biologic feature of only being able to infect a single mammalian species²⁷; for example, organisms isolated from mice are incapable of infecting other mammals, even those as closely related as the rat. This restricted transmission is consistent with studies demonstrating unique phenotypes and genotypes of *Pneumocystis* isolated from each mammalian host studied to date.^{25,29,58,69,84} The obvious implication of this biologic property is that the source of *Pneumocystis* causing PCP in humans must be other humans.

The host species specificity and restricted transmission have led to discussions regarding whether these features represent distinct species of *Pneumocystis*. Efforts have been made to adopt new nomenclature for *Pneumocystis*, primarily to distinguish between strains derived from humans and strains from lower mammals. In 1976, Frenkel suggested *Pneumocystis jiroveci* n. sp. for isolates from humans.²³ During the ensuing three decades this term was not used. In 1988, Hughes and Gigliotti³⁷ proposed a nomenclature merely designating the host from which the organism was obtained (e.g., *Pneumocystis carinii*, *humanus*; *P. carinii*, *rattus*). In 1994, Stringer and the *Pneumocystis* Workshop⁷¹ used DNA sequence data to employ a “special forms” designation (e.g., *P. carinii* f. sp. *hominis*). A subsequent system put forth in 2002 by Stringer and colleagues⁷⁰ is currently used by some investigators and designates the human form as *P. jiroveci* Frenkel. *P. jiroveci* is being increasingly used to designate *Pneumocystis* that infects humans. However, because issues have been raised regarding this new nomenclature, some authors use only the genus name when describing this organism.^{26,34,43,70}

TRANSMISSION AND EPIDEMIOLOGY

Transmission

Pneumocystis is spread by the airborne route.³⁵ *Pneumocystis* has been isolated from a wide variety of animal species from all over the world.

Because *Pneumocystis* organisms isolated from different mammalian hosts are morphologically quite similar, it was initially thought that PCP in humans was a zoonotic infection stemming from contact with infected animals. As noted earlier, it is now clear that transmission between two different mammalian species is highly unlikely. Longitudinal serologic studies starting just after birth demonstrate that most children are infected with *Pneumocystis* by 2 years of age.⁷⁷ These serologic data are substantiated by the finding of *Pneumocystis* in the lungs of many infants who have died of sudden infant death syndrome.^{54,78} Infection of a normal host early in life could result in the establishment of a latent infection, as happens in the case of tuberculosis. This was believed to be the case with *Pneumocystis* when infection in the immunocompromised host was postulated to be the result of reactivation of a latent *Pneumocystis* infection.¹³ However, under controlled experimental conditions, normal mice were shown to control *Pneumocystis* after infection in a typical pattern of infection, immune response, and resolution of infection.³ Furthermore, latent infection does not occur after immune-mediated resolution of infection.¹⁰ When infected, but before resolution of infection, immunologically normal mice can transmit *Pneumocystis* to another mouse.³⁰ If the recipient mouse is normal, a subclinical infection occurs. This cycle, if repeated, would serve to maintain *Pneumocystis* in the population. If instead the recipient mouse is immunocompromised, then full PCP results.

By using information gained from animal models and observational studies, it is possible to propose a likely transmission cycle for *Pneumocystis*. Seronegative infants who are continuously introduced into the population present a large pool of susceptible humans who become transiently infected. Infection can be either asymptomatic or mildly symptomatic.⁷⁷ In either case, the infection is transmissible. Continued passage from normal host to normal host would serve as a reservoir of *Pneumocystis* that when transmitted to an immunocompromised individual results in life-threatening PCP. Consistent with this model, molecular studies suggest that a second case of PCP occurring more than 6 months after the first episode is most likely the result of reinfection with a new strain of *Pneumocystis*.⁴⁵ It is not known whether subclinical reinfection of adults can serve as another reservoir of *Pneumocystis*, but the finding of microscopically visible organisms rarely has been documented in adults.

Pneumocystis Pneumonia and AIDS

AIDS was brought to the attention of the medical community in the United States as a result of a small cluster of cases of PCP in previously healthy young men,⁸ and PCP remains the most common AIDS-defining illness. It was reported in 39% of 2786 pediatric AIDS patients reported to the Centers for Disease Control and Prevention (CDC) through 1990 and in 75% of untreated adults with AIDS, and more than half of adults dying with AIDS have had at least one episode of PCP.^{43,67} The key determinant in host defense against PCP is the CD4⁺ T cell. Although the precise role of CD4⁺ T cells in protection against PCP has not been defined, it is clear that any condition that interferes with CD4⁺ T-cell number or function puts the patient at risk for developing PCP. Because the pathogenesis of AIDS involves the destruction of CD4⁺ T cells, it is easy to identify at-risk patients simply by checking CD4⁺ T-cell counts. Adults whose CD4⁺ T-cell counts fall below 200/ μ L are at high risk for developing PCP. The determination of risk for PCP in children with AIDS is based on age because CD4⁺ T-cell counts are very high at birth, fall rapidly during the first year of life, and then fall more slowly to reach adult levels around 6 years of age. Thus children with AIDS are at high risk for developing PCP if they are younger than 1 year with CD4⁺ T-cell counts less than 1500/ μ L; 1 to 5 years of age

FIG. 225.1 Typical cyst forms shown by Gomori silver methenamine stain of lung tissue obtained by open lung biopsy from a 20-month-old child with severe combined immunodeficiency disease (A, $\times 100$; B, $\times 100$).

with counts less than 500/ μL ; and older than 5 years with counts less than 200/ μL .

Pneumocystis Pneumonia Not Associated With AIDS

The other large group of patients at risk for PCP is those with congenital immunodeficiencies involving T- and B-cell function and those with medical conditions requiring immunosuppressive therapy, such as malignancies. For this latter group, it is important to remember that it is generally the therapy and not the underlying disease that puts the patient at risk for developing PCP. This was clearly demonstrated in children with acute lymphocytic leukemia when those receiving one, two, or three chemotherapeutic agents had an incidence of PCP between 2% and 5%, whereas in those receiving four drugs the incidence was 22%.³⁰ Likewise, the addition of radiation therapy to a three-drug chemotherapeutic regimen increased the incidence of PCP to as high as 35%.³⁷ Thus it is important to keep in mind that as therapies change, so, too, does the risk for developing PCP. For example, PCP was rarely seen in patients with Crohn disease receiving conventional immunosuppressive therapy. However, PCP is now a well-recognized complication of Crohn disease since the addition of anti-tumor necrosis factor (TNF) therapy to the treatment regimen.⁴⁴

The incidence of PCP seems to be increasing, possibly owing to the increasing use of biologic response modifiers, such as anti-TNF agents, and newer, more potent immunosuppressive drugs. Reports from cancer centers show that the incidence or prevalence, or both, of PCP has increased in this population.^{58,85} Similar increases are reported among patients receiving organ transplants, those with autoimmune diseases, and those who have had a bone marrow transplantation.^{4,57,75}

In contrast to patients with AIDS, in which there is consensus on the guidelines for starting PCP prophylaxis, the risk for developing non-AIDS-associated PCP can be more difficult to predict. This is because the immunosuppressive regimen affects not only cell number but also cell function. Thus a patient on chemotherapy may have a

CD4⁺ T-cell count above the risk threshold seen in AIDS patients, but if function is suppressed then the risk for PCP increases. Because T-cell function is not routinely measured in clinical laboratories, physicians must rely on cumulative clinical experience when judging the need for PCP prophylaxis.

IMMUNOPATHOGENESIS

Pneumocystis is the classic opportunistic pathogen: it is incapable of producing overt pneumonia in the immunologically normal host, yet in the immunocompromised host PCP is universally fatal if untreated. Even with treatment the mortality is high, ranging from 5% to 25%, depending on the patient population.

The occurrence of PCP in patients with AIDS and pure T-cell deficiency disease provides indirect evidence of the potential importance of cellular immunity in protecting the host against this opportunist. Direct evidence for the necessity of CD4⁺ T cells comes from mouse studies showing that depletion of this cell population renders the mouse susceptible to PCP. Less well appreciated is the evidence for the importance of humoral immunity in protection against *Pneumocystis*. For example, PCP occurs in patients with agammaglobulinemia or hyperimmunoglobulin M syndrome and mice with a variety of genetically engineered defects in antibody response pathways have been demonstrated to be susceptible to PCP.

The host response to *Pneumocystis* is likely the critical determinant of the severity of lung injury occurring as a result of PCP.²⁸ Three clinical observations support the importance of the inflammatory response in the outcome of PCP: (1) neutrophil number, but not organism counts, in lung secretions correlates with higher morbidity and mortality⁵⁰; (2) the differential in mortality between AIDS-related and non-AIDS-related PCP⁵¹; and (3) the ability of PCP to trigger the immune reconstitution inflammatory syndrome (IRIS).⁵⁶

In recent years, the application of molecular technology has provided a vast amount of information to aid in understanding the immunopathogenesis of PCP.²⁸ When *Pneumocystis* reaches the lungs of a normal host by the airborne route, the organism elicits what we have termed a balanced immune response and the subject remains asymptomatic or mildly symptomatic while the infection is cleared. Alternatively, if the host is severely immunocompromised owing to insufficient CD4⁺ cells, a life-threatening pneumonitis develops, driven by CD8⁺ T cells. Because CD8⁺ T cells are a critical determinant of the lung injury, without controlling organism burden, we have termed this response *ineffective inflammation*. Finally, in the setting of return of CD4⁺ T cells, such as after institution of treatment for human immunodeficiency virus (HIV) infection or during engraftment after bone marrow transplantation, one may see an exaggerated but effective response, as seen in IRIS, that clears the *Pneumocystis* but at the expense of significant lung injury.

Alveolar macrophages play a critical role in pulmonary host defense and contribute to both innate and adaptive immune responses. Alveolar macrophages have long been thought to serve as the effector cell for clearing *Pneumocystis* organisms from the lung, but these cells are not capable of controlling *Pneumocystis* infection in hosts with impaired CD4⁺ T-cell function. A recent study utilizing an animal model of PCP has demonstrated that macrophage phagocytosis is the effector mechanism for the CD4⁺ T-cell-mediated clearance of *Pneumocystis* organisms from the lung, indicating that the adaptive immune response must direct the macrophage-mediated clearance of this fungal pathogen.⁸¹ In addition to host defense, macrophages also likely contribute to the immunopathogenesis of PCP. Macrophages are significant sources of proinflammatory cytokines, including TNF- α and interleukin-1 (IL-1), and *Pneumocystis* β -glucan is a potent stimulator of the alveolar macrophage cytokine response.⁴⁷ Therefore, in addition to their function in host defense, alveolar macrophages may also contribute to PCP-related lung injury through elaboration of inflammatory mediators.

The proinflammatory cytokines TNF- α and IL-1 are required for host defense against *Pneumocystis* infection^{11,12} but also contribute to the immunopathology associated with PCP. These cytokines, acting through chemokine signals, promote neutrophil, lymphocyte, and monocyte recruitment to the lung, which may cause alveolar damage and diminished gas exchange, resulting in respiratory failure. Importantly,

mice lacking TNF receptors are partially protected from PCP-related respiratory impairment and weight loss.⁸³ Other cytokines associated with helper T-cell type 1, 2, or 17 responses may also modulate host defense and PCP-related immunopathogenesis by regulating alveolar macrophage phenotype and activation state, but these issues need further clarification.

Surfactant phospholipids and apoproteins are critical to lung function and are adversely affected by *Pneumocystis* infection. Patients with PCP display dramatic alterations in surfactant function and composition,⁶⁵ which is likely an important determinant of disease severity. In vitro studies have determined that *Pneumocystis* organisms interact directly with pulmonary surfactant to reduce its surface tension—lowering properties.⁸⁰ Furthermore, studies in animal models have found that *Pneumocystis*-driven inflammation also contributes to surfactant dysfunction in the setting of PCP.^{5,82} Anecdotal reports describe some benefit from the administration of exogenous surfactant to patients with PCP.¹⁵

PATHOLOGY

The pathologic findings of *Pneumocystis* infections are, with rare exceptions, limited to the lungs. Rarely, *Pneumocystis* organisms have been detected in the lymph nodes, spleen, liver, retina, bone marrow, gastrointestinal tract, pancreas, heart, adrenals, and peripheral blood.⁷³

In the infantile “epidemic” form of disease, essentially all alveoli contain large numbers of organisms. Extensive interstitial plasma cell infiltrates distend the alveolar walls five to 20 times over their normal thickness, and almost no intraalveolar fibrinous exudate is noted.³³

The progression of disease in childhood and adult forms of PCP can be divided into three pathologic stages.^{33,61} An initial stage is characterized by the presence of cysts and trophozoites attached, possibly by fibronectin, to the alveolar walls.⁶⁰ No septal inflammatory or cellular response is evident, and no clinical disease is associated with this stage. A second stage, which may or may not be associated with clinical signs and symptoms, is characterized by desquamation of alveolar cells and an increase in the number of cysts within alveolar macrophages. TNF may be a major mediator involved in the killing of *Pneumocystis* by activated alveolar macrophages and may be induced by oxidative stress in the alveoli.⁵⁹ The final stage is typified by extensive reactive and desquamative alveolitis manifested by marked cytoplasmic vacuolization of macrophages, mononuclear and plasma cell infiltrates within alveolar septa, and clusters of organisms located predominantly within macrophages in the lumen of alveoli. The histopathology of this final stage definitely is associated with clinical manifestations of pneumonitis.⁶¹

CLINICAL MANIFESTATIONS

Hypoxia is the hallmark of PCP. The natural course of *Pneumocystis* infection varies greatly and depends primarily on the status of host defenses in individual patients. The onset may be insidious, with a clinical course of 3 weeks or more, or may be fulminant and rapidly progressive over a few days. For example, AIDS patients are probably more immunocompromised than oncology patients at the point in time when they develop PCP, as evidenced by typically higher organism burdens, yet AIDS patients are more likely to have a longer history of symptoms and a lower mortality rate than non-AIDS patients.^{51,72}

Symptoms in immunosuppressed children or adults without AIDS may be more abrupt in onset and rapidly progressive, but, even with these patients, the course varies greatly.^{6,31} The mortality rate approaches 100% in untreated cases. In cases in children and adults, in contrast to infantile cases, fever generally is present and of high grade. It often precedes the onset of nonproductive cough, tachypnea, and severe dyspnea. Fever, tachypnea, and the radiographic appearance of pulmonary infiltrates, in that sequence, 1 to 21 days before diagnosis was established, occurred in a group of children with malignancies. The time of onset of clinical disease in non-AIDS, high-risk patients is unpredictable, but disease often occurs after discontinuance or a reduction in the dose of corticosteroid therapy.⁶ Patients with severe combined immunodeficiency disease who receive a bone marrow transplant subsequently may contract fulminant PCP when apparent immunologic reconstitution has occurred.⁶

FIG. 225.2 Typical diffuse interstitial infiltrates seen in a 20-month-old child with severe combined immunodeficiency disease at the time of evaluation for clinical *Pneumocystis carinii* pneumonitis.

These observations support the hypothesis that the clinical features early in the course of PCP are dependent to a large extent on the patient's ability to mount an inflammatory response.

Infants and children with AIDS may have a more insidious onset of PCP and therefore may come to medical attention later than non-AIDS patients. In this scenario, the patient is usually acutely ill with fever, cough, dyspnea, tachypnea, and an alveolar-arterial oxygen gradient greater than 30 mm Hg at the time of diagnosis.¹⁴

In children and adults with and without AIDS, physical examination at the time of initial evaluation may reveal tachypnea; nasal flaring; and intercostal, subcostal, or suprasternal retractions. An ashen color or cyanosis may be present or may develop rapidly. Auscultation of the chest frequently is characterized by a conspicuous absence of adventitious sounds despite the presence of rapid (80–100 breaths/min), shallow respirations. Scattered rales, rhonchi, or wheezes most often are detected later in the clinical course as resolution occurs. Aside from variable elevation in temperature, few other physical abnormalities are noted except those referable to pulmonary disease or secondary to the patient's underlying disease or treatment.^{6,31}

Various radiographic abnormalities have been observed in documented cases of isolated PCP.^{19,22} These variations result partly from observations at different stages in the course of disease. Bilateral diffuse parenchymal infiltrates (Fig. 225.2) occur most commonly, but no pattern is sufficiently specific either to exclude or to confirm a diagnosis of PCP. Although initially a reticulogranular interstitial process, *Pneumocystis* pneumonitis progresses to a predominantly alveolar process with coalescence and air bronchogram formation. Late in the course of the disease, lung fields may opacify completely. Unusual radiographic findings, including an asymmetric distribution, consolidated lobar infiltrates, pneumothorax and pneumomediastinum, localized parenchymal nodular densities, and pleural effusion, have been documented.¹⁹ During treatment, radiographs show gradual clearing after a variable latent period, during which they may appear worse. Residual interstitial fibrosis occurs in a small percentage of patients.

DIAGNOSIS

The clinical features associated with PCP are not sufficiently specific to differentiate it from other opportunistic pulmonary infections. Mixed infections with viral, bacterial, fungal, or parasitic agents have been documented along with *Pneumocystis*. Implicit in these observations is the importance and urgency of establishing a definitive diagnosis before the institution of specific therapy. An etiologic diagnosis can be ascertained only by the demonstration of *Pneumocystis* organisms in lung tissue or respiratory secretions.

Numerous techniques have been used to obtain suitable material for diagnostic purposes. Specimens obtained by noninvasive methods, especially from induced sputum or tracheal aspirate, have been used to reveal *Pneumocystis*, and the sensitivity of these methods is 50% to 60%. Bronchoalveolar lavage is quite reliable, with a sensitivity of 90% to 95%.¹⁶ Other methods of obtaining a specimen, such as endobronchial brush biopsy, transbronchial lung biopsy, or percutaneous needle aspiration, have been used successfully to establish a diagnosis of PCP, but are not commonly used since the advent of bronchoalveolar lavage.

If PCP remains a possibility after using the just-noted diagnostic methods, one should proceed to an invasive technique such as open-lung biopsy. Open-lung biopsy provides the most dependable specimen from which identification of the organism and the extent of the infection can be ascertained.¹ The chief disadvantage is the need for general anesthesia.

For diagnostic purposes, the methenamine silver nitrate method of Gomori and the less widely used, but more rapid, toluidine blue O and calcofluor white stains are most useful for showing cyst forms in tissue sections, aspirates, or imprints. For more detailed morphologic study of intracystic sporozoites and trophozoites, polychrome stains, including Giemsa, Wright, Gram, and methylene blue stains, are more suitable. In tissue sections, the Gomori stain, in combination with hematoxylin and eosin staining, allows study of the organism and host tissue. A direct immunofluorescent monoclonal antibody technique has become commercially available.⁶² Serologic methods are not useful for diagnostic purposes.

There are a large number of studies describing detection of *Pneumocystis* DNA by polymerase chain reaction. Although this has proved to be a valuable laboratory technique, it has had limited use in clinical situations. Reported sensitivities are excellent, but specificities can be less than 85% to 90%.^{2,74} At this time, polymerase chain reaction remains a research tool and is not widely used in general clinical practice.

Hematologic studies are of no diagnostic value, primarily because of baseline abnormalities reflecting the underlying disease of affected patients. Eosinophilia has been reported in isolated cases but usually is not present. Depressed serum total protein and albumin values frequently are noted because of the poor nutritional status of

representative patients. Lactate dehydrogenase activity is increased, but it is not a specific marker for PCP and is of little diagnostic benefit.⁷⁹

PROGNOSIS

Before the availability of specific therapeutic agents, the overall prognosis of patients with PCP was poor. Despite supportive care, almost 100% of infected patients with underlying neoplastic or immunodeficiency disorders died, whereas approximately 50% of infants in the European epidemics died as a result of this pulmonary infection. With modern medical management, the prognosis for patients with PCP depends to some extent on the underlying risk factor for PCP. For example, the mortality for PCP in cancer patients (25–40%) is four to five times higher than for those with AIDS (5–10%).⁵¹ Patients who require mechanical ventilation have mortality rates in excess of 60% to 70%. A similar high mortality is seen in infants with PCP whose disease progresses and who then require mechanical ventilation.⁶⁶

TREATMENT

Trimethoprim-sulfamethoxazole is the drug of choice for both the treatment and prevention of PCP.^{38,46} A minimum of 2 weeks of therapy is recommended for non-AIDS patients; 3 weeks may be optimal for patients with AIDS. The CDC, the National Institutes of Health, and the Infectious Diseases Society of America have provided consensus guidelines for the treatment and prevention of PCP in immunosuppressed patients (Table 225.1).⁷ Atovaquone, a hydroxynaphthoquinone approved by the US Food and Drug Administration, is effective and has few side effects (rash, nausea, and diarrhea). It can be administered only by the oral route.⁴² The sulfone dapsone has been evaluated in children²⁴ and may be used alone but is synergistic with trimethoprim⁴⁹ against *P. jiroveci*. Dapsone may cause rashes, neutropenia, thrombocytopenia, anemia, and methemoglobinemia. Clindamycin plus primaquine has also been used.⁶⁴

Some studies in adults with AIDS and PCP suggest that the administration of corticosteroids early in the course of moderately severe pneumonitis reduces the occurrence of respiratory failure and improves

TABLE 225.1 Dosing Recommendations for the Prevention and Treatment of *Pneumocystis* Pneumonia

Indication	First Choice	Alternative	Comments/Special Issues
Primary prophylaxis	Trimethoprim 5 mg/kg with sulfamethoxazole 25 mg/kg (TMP-SMX) daily generally divided into two doses. The total daily dose should not exceed 1600 mg SMX and 320 mg TMP. Several dosing schemes have been used successfully: given 3 days per week on consecutive days or on alternate days; given 2 days per week on consecutive days or on alternate days; or given every day.	Dapsone (children ≥ 1 mo), 2 mg/kg (maximum, 100 mg) orally daily or 4 mg/kg (maximum, 200 mg) orally weekly. Atovaquone (children aged 1 to 3 mo and >24 mo, 30 mg/kg orally daily; children aged 4 to 24 mo, 45 mg/kg orally daily) Aerosolized pentamidine (children aged ≥ 5 y), 300 mg every month via Respirgard II nebulizer	<i>Primary prophylaxis indicated for:</i> All HIV-infected or HIV-indeterminate infants aged 4–6 wk to 12 mo regardless of CD4 count/percentage; HIV-infected children aged 1–5 y with CD4 count <500 cells/mm ³ or CD4 percentage $<15\%$; HIV-infected children aged 6–12 y with CD4 count <200 cells/mm ³ or CD4 percentage $<15\%$. <i>Criteria for discontinuing primary prophylaxis:</i> Do not discontinue in children aged <1 y. After ≥ 6 mo of HAART and Age 1–5 y, CD4 percentage or count is $\geq 15\%$ or ≥ 500 cells/mm ³ for >3 consecutive months or Age ≥ 6 y, CD4 percentage or count is $\geq 15\%$ or ≥ 200 cells/mm ³ for >3 consecutive mo <i>Criteria for restarting primary prophylaxis:</i> Age 1–5 y with CD4 percentage $<15\%$ or count <500 cells/mm ³ Age ≥ 6 y with CD4 percentage $<15\%$ or count <200 cells/mm ³
Secondary prophylaxis (prior <i>Pneumocystis</i> pneumonia [PCP])	Same as for primary prophylaxis	Same as for primary prophylaxis	Secondary prophylaxis indicated for children with prior episode of PCP. <i>Criteria for discontinuing secondary prophylaxis:</i> same as for primary prophylaxis. <i>Criteria for restarting secondary prophylaxis:</i> same as for primary prophylaxis.

Continued

TABLE 225.1 Dosing Recommendations for the Prevention and Treatment of *Pneumocystis* Pneumonia—cont'd

Indication	First Choice	Alternative	Comments/Special Issues
Treatment	TMP-SMX 15–20 mg/kg TMP plus 75–100 mg/kg SMX daily given orally in three to four divided doses given for 21 days (followed by prophylaxis dosing)	<i>If TMP-SMX intolerant or clinical treatment failure after 5–7 days of TMP-SMX therapy:</i> Pentamidine 4 mg/kg IV once daily is first-choice alternative regimen (pentamidine may be changed to atovaquone after 7–10 days IV therapy) Atovaquone 30–40 mg/kg (maximum, 1500 mg/day) orally in two divided doses with food for patients from birth to 3 mo and ≥24 mo. For infants from 3–24 mo, an increased dose of 45 mg/kg daily in two divided doses with food is needed.	After acute pneumonitis resolved in mild-moderate disease, IV TMP-SMX may be changed to oral dosing. Dapsone 2 mg/kg orally once daily (maximum, 100 mg/day) plus trimethoprim 15 mg/kg/day orally divided into three doses has been used in adults, but data in children are limited. Primaquine base 0.3 mg/kg orally once daily (maximum, 30 mg/day) plus clindamycin 10 mg/kg IV or by mouth (maximum 600 mg given IV and 300–450 mg given orally) every 6 h has been used in adults, but data in children are not available. <i>Indications for corticosteroids:</i> Pao ₂ <70 mm Hg at room air or alveolar-arterial oxygen gradient >35 mm Hg. Prednisone dose: 1 mg/kg orally twice daily for 5 days, then 0.5–1 mg/kg orally twice daily for 5 days, then 0.5 mg/kg orally once daily for days 11 to 21. Chronic suppressive therapy (secondary prophylaxis) with TMP/SMX is recommended in children and adults after initial therapy.

oxygenation.⁵⁵ Other studies show no benefit from corticosteroids.¹⁸ Limited studies of this supportive therapy have been reported to increase survival in children.⁶⁸ When used, a reasonable approach seems to be to withdraw corticosteroid therapy as soon as pulmonary function has become stabilized.

PREVENTION

PCP can be prevented in more than 95% of patients at high risk for acquiring the disease.^{41,32,39} Patients in high-risk groups, such as patients with cancer, acquired and congenital immunodeficiency disorders, and organ or bone marrow transplants or those receiving intensive immunosuppressive therapy, should be placed on a chemoprophylaxis regimen throughout the risk period (see Table 225.1).

Because of the high risk for acquiring PCP during the first year of life, often before HIV infection is recognized, PCP prophylaxis should be initiated at 4 to 6 weeks of age in all infants born of HIV-infected women, regardless of CD4⁺ lymphocyte cell counts. The use of chemoprophylaxis in this age group has been highly effective in HIV-infected infants.⁶³ When infants are shown not to be infected with HIV, prophylaxis may be discontinued. HIV-infected infants and infants with undetermined status should be continued on prophylaxis during the first year of life. At 1 year of age and subsequently, the use of chemoprophylaxis is based on the CD4⁺ lymphocyte count and other AIDS-defining features.

Trimethoprim-sulfamethoxazole given 3 days per week is the preferred drug for chemoprophylaxis. For patients unable to take trimethoprim-sulfamethoxazole, dapsone 2 mg/kg per day or 4 mg/kg per week is suggested.²⁴ Studies in adults show that daily doses of dapsone⁵³ or one dose of dapsone per week⁴⁰ is effective prophylaxis.⁵² An alternative to dapsone is aerosolized pentamidine 300 mg monthly through Respigard II inhaler.⁴⁸ The dosage for aerosolized pentamidine is the same as the dosage for adults.⁴⁸ Atovaquone has been shown to be effective and safe in children.¹⁷ A controlled study compared prophylaxis with atovaquone and azithromycin with trimethoprim-sulfamethoxazole in 366 high-risk, HIV-infected children.³⁶ The regimens were similar in effectiveness in prevention of bacterial infections, and PCP occurred with equal frequency.

Studies in adults and children show that PCP prophylaxis can be discontinued safely in patients responding to highly active antiretroviral therapy with a sustained increase in CD4⁺ T lymphocytes to levels above the risk threshold for PCP (see Table 225.1).

Patients are protected from pneumonitis only while receiving chemoprophylaxis and become susceptible again when use of the drugs is discontinued. No vaccine is available.

Parasitic Nematode Infections

226

Peter J. Hotez

INTESTINAL NEMATODES

The three major intestinal nematodes of children, *Ascaris lumbricoides*, *Trichuris trichiura*, and the hookworms (led by *Necator americanus*), together have a substantial impact on the health and well-being of children living in less-developed nations of the world.⁵ This “unholy trinity” of soil-transmitted helminths (STHs), or “geohelminths,” deprives hundreds of millions of young children of their full intellectual and growth potential. Some estimates suggest that 2 billion people are infected with STHs, 300 million of whom have severe morbidity. According to the World Health Organization (WHO) an estimated 800 million children are at risk for STHs in low- and middle-income countries.³³ Building on studies from the early part of the 20th century,^{24,25} extensive data from many different geographic regions confirm that chronic intestinal nematode infections acquired during childhood suppress cognitive and intellectual development^{7,22,25} and impair physical growth and fitness.^{9,29,30,28} Through these mechanisms the STH infections can actually cause poverty in the world’s developing countries.¹³ Because many of these detrimental effects are reversible with the use of anthelmintic drugs to eliminate nematodes from the intestinal tract,^{29,30} several investigators and international relief agencies have advocated the administration of benzimidazole anthelmintics (sometimes known as “deworming”) as a cornerstone of public health programs directed at school-aged children.^{5,6,23}

A 2001 World Health Assembly resolution urges its member states to “deworm” at least 75% and up to 100% of school-aged children at risk for acquiring STH infections through programs of mass drug administration (MDA). Additional studies also point to the benefits of deworming preschool-aged children.² For both populations single-dose benzimidazole drugs, either albendazole (400 mg) or mebendazole (500 mg), are most commonly used. Globally, efforts are under way to link deworming for STH infections with MDA for other neglected tropical diseases, including lymphatic filariasis, onchocerciasis, and trachoma,^{13,16,10} as well as linking deworming to the control of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), malaria, and tuberculosis.¹⁵

In some highly endemic areas, reinfection with *A. lumbricoides*, *T. trichiura*, and hookworms occurs within 6 months of receiving anthelmintic treatment.³ Therefore, MDA is not always a practical means of control, unless the drugs are used frequently. Newer information suggests that the efficacy of single-dose anthelmintic drugs used for MDA may not be as high as believed previously.¹⁹ Thus, although single-dose benzimidazoles are generally highly effective against pediatric ascariasis, they are less effective against hookworm infection or trichuriasis.^{1,26} Such observations may explain why a Cochrane analysis inconsistently demonstrated the health benefits of deworming,³¹ as well as why over the last 2 decades there have been dramatic decreases in the global prevalence of ascariasis, but not hookworm infection and trichuriasis.⁸ Concern about the potential for emerging anthelmintic drug resistance also exists. Some researchers have pointed to the use of genetically engineered anthelmintic vaccines, especially for hookworm, as one possible solution to the problem of worm reinfection and disease during childhood.^{12,34}

Still another public health concern about the long-term effects of STH infections is evidence suggesting that they may promote the susceptibility to, or worsen the severity of, malaria and HIV infection or AIDS.¹⁷ Interest has developed in examining the impact of large-scale

deworming on these killer diseases.^{15,20} Information also indicates the potential impact of parasitic infections, including the STH infection toxocariasis, in developed countries such as the United States and Europe.^{14,10,21,27} In the United States, hardly any of the therapeutic regimens for STH infections are approved by the US Food and Drug Administration, in part because there have been few if any incentives for pharmaceutical companies to pursue indications for these orphan diseases. Also of concern is the high cost of some of these anthelmintic drugs, many of which are generic but monopolized by just a few companies.⁴

In addition to the long-term effects seen when children harbor numerous intestinal nematodes are the increasingly recognized unique neonatal and infantile syndromes that information indicates may result from vertical transmission of the infective stages of some intestinal nematodes, probably in colostrum and breast milk.^{5,11} The best-documented example of vertical transmission in infants results in the “swollen belly syndrome” caused by *Strongyloides fuelleborni kellyi*, although other perinatal nematode infections probably also occur (see later). Another emerging pediatric neurologic syndrome (and cause of epilepsy) of great concern (but of unknown etiology) is so-called “nodding syndrome” that has become endemic among some school-aged children and adolescents living in onchocerciasis-endemic areas of South Sudan and Uganda.³² Finally, children experience significant morbidity during zoonotic transmission of the infective stages of intestinal nematodes in companion animals such as dogs and cats. The resultant aberrant migration of these foreign nematode larvae has become a major pediatric public health problem in large urban areas of the United States and Europe.^{14,18}

Ascaris lumbricoides

Ascariasis is one of the most prevalent infections in the world,^{44,45} with an estimated 804 million people chronically infected with *A. lumbricoides*.^{5,8} Currently, the greatest numbers of cases of ascariasis occur in East Asia, Southeast Asia, and the Indian subcontinent.^{5,59} Surveys conducted in rural southern communities of the United States during the 1970s indicated that the prevalence of ascariasis was 20% to 67%.³⁷ Those rates most likely have declined significantly over the past decades, however.^{10,27}

Ascaris infection, when relatively light, is usually not apparent until the patient passes an adult worm through the rectum or a worm emerges from the nasopharynx. In heavy infections, constitutional symptoms may occur during the early phase, and intestinal malabsorption and obstruction may occur in the later phase. The infection is acquired by ingestion of the infective eggs, which hatch in the upper part of the small intestine and free the larvae. The larvae penetrate the intestinal wall, reach venules or lymphatics, and pass through the portal circulation to the liver, the right ventricle, and the lungs.

In the lungs, the larvae break out of the capillaries and begin ascending through the respiratory radicles until they reach the glottis; passing over the epiglottis, they enter the esophagus and are carried down to the small intestine, where they mature and become adult worms. The adult female *Ascaris* produces huge numbers of eggs—possibly 200,000 a day. To ensure adequate quantities of egg-requiring cholesterol, the parasite sequesters oxygen through a specially modified hemoglobin.⁴⁷ The entire cycle, beginning with the infective eggs and resulting in ovipositing females, lasts approximately 2 months. Infection is maintained in the community by the deposition of human stool in soil, which permits embryonated eggs to develop into the infective stage. This

process takes approximately 2 weeks. The high prevalence of infection results not only from deficient sanitary facilities for disposal of human excreta but also from the deliberate use of human feces as fertilizer.

Epidemiology

In many regions of the developing world, *Ascaris* eggs are almost ubiquitous in the environment. All ages are affected by the parasite; young children, who are exposed more often to the contaminated soil, are affected most frequently. These children usually harbor greater numbers of adult worms in their intestine than do adults living under similar conditions.^{29,30,28,43} High worm burdens in children also occur with *Trichuris* infections (see later). Because the phenomenon of heavy *Ascaris* and *Trichuris* worm burdens in childhood is found throughout most of the developing world, pediatric predisposition to “worminess” is widely thought to have a possible genetic or immunologic basis.⁹

Ascaris eggs are extremely hardy and resistant to extremes of temperature and desiccation, features that may explain the common finding of high rates of ascariasis in impoverished urban environments (e.g., Guatemala City, Mexico City) and in rural environments. The eggs also are resistant to chemical disinfectants and are not destroyed readily by sewage treatment. In some areas, pigs may serve as a reservoir for zoonotic *Ascaris* infection.³⁶

Pathophysiology

During the migratory phase of the infection, the larvae evoke an inflammatory response associated with eosinophilic infiltration. *Ascaris* antigens—so-called ABA-1 allergen—released during the molting of larvae evoke an immune response, and immunoglobulin E (IgE) antibodies directed against ABA-1 may be associated with parasite resistance.⁵⁵ However, through these mechanisms ascariasis is considered a major cause of asthma in impoverished areas of the world.^{35,38,63} *Ascaris* larvae also release immunomodulatory glycosphingolipids that inhibit T-helper type 1 (Th1) responses.^{5,43} Chronic ascariasis and trichuriasis may suppress host inflammation and even responses to vaccines by promoting a Th2-type cytokine profile.⁶⁰ There are also data to support a role for ascariasis in promoting susceptibility to malaria,²⁰ although not all studies confirm this finding, and some even suggest a possible protective effect.⁵⁷ During the intestinal stage of infection, symptoms derive primarily from the physical presence of the worms in the gut, from aberrant migration into other lumina, or from perforation into the peritoneum. As a protective mechanism for its own survival, *Ascaris* secretes peptides that block the action of pancreatic digestive enzymes (trypsin, chymotrypsin, elastase),^{48,51} a feature that may play a role in parasite-associated nutrient malabsorption, including the malabsorption of vitamin A.⁴² Ascariasis also results in lactose intolerance.⁴² Whether these phenomena provide the basis of observed *Ascaris*-associated physical growth retardation during childhood is unknown.^{7,29,30,28,43,56}

Clinical Manifestations

The degree of disease induced by the migratory phase of *Ascaris* is related directly to the number of larvae migrating simultaneously. In light infections, this phase is typically unrecognized. Heavy infection, such as that induced in himself by Koino,⁵³ who swallowed 2000 infected eggs, may cause severe pneumonitis. In some regions of the world, pediatric *Ascaris* pneumonitis is seasonal and can resemble a seasonal form of asthma associated with eosinophilia.^{5,46}

In the lumen of the intestine, *Ascaris* adult worms may become matted together and form a bolus large enough to cause intestinal obstruction, sometimes leading to bowel infarction and intestinal perforation. This is a particular problem in very young children because of the small luminal diameter of their intestines.⁵² The incidence of this complication has been estimated at 2 per 1000 infected children per year.³⁷ Children with *Ascaris* obstruction exhibit a toxic appearance, often with signs and symptoms of peritonitis.⁵ When recognized early, the obstruction can be treated with medical management, but in many cases surgical intervention is mandatory. Ascariasis has also been linked to chronic intussusception.⁵⁸

Hepatobiliary and pancreatic ascariasis (HPA) results from blockage of the bile duct and pancreatic duct. Patients with HPA are subject to cholecystitis, acute cholangitis, “biliary colic,” acute pancreatitis, or

hepatic abscess.⁵² In contrast to intestinal obstruction, HPA tends to be more common in adults, especially women.⁵² Certain irritants, such as halogenated hydrocarbons (e.g., carbon tetrachloride and tetrachloroethylene, used in the past to treat certain hookworm infections), elevation of body temperature, and general anesthesia, have been known to precipitate aberrant migration. *Ascaris* screening by fecal examination should be considered before performing elective surgery on a child who may have immigrated recently from an impoverished area of the tropics.

Whatever the mechanism of interference by *Ascaris* with growth or nutrition, treatment with anthelmintics leads to substantial catch-up growth in previously parasitized children.^{7,29,30,28,54,56} Ascariasis in pregnant women results in intrauterine growth retardation.⁶² Most individuals with light infections rarely are symptomatic (they become aware of the parasites by passage of adult worms in stool or through regurgitating and vomiting the adult worms), although researchers have conjectured that even these individuals may exhibit subtle deficits in cognitive and intellectual development.⁷

Several cases of neonatal ascariasis have been described in the literature.^{39,41} The mode of acquisition of these infections is unknown, but canine and feline ascarid infections commonly are acquired by a transplacental route, suggesting the possibility that this route also may occur in humans.

Diagnosis and Differential Diagnosis

The differential diagnosis of pneumonia caused by *Ascaris* suggests a parasitic etiology because of the peripheral eosinophilia. Any nematode with a migratory phase through the lungs can mimic this infection, however. *Ascaris* must be considered as a cause of intestinal obstruction in any geographic locale where its prevalence is high.

The diagnosis of intestinal ascariasis is established by identifying the characteristic ascarid eggs through microscopic examination of stool. Efforts have been made more recently to detect *Ascaris* metabolites in the urine by gas-liquid chromatography^{49,50} or parasite DNA.⁴⁰ HPA is suspected in heavily infected children who have signs of biliary obstruction. Ultrasonography and endoscopic retrograde cholangiopancreatography are useful adjunctive diagnostic procedures for these conditions.⁵²

Treatment

For an ordinary *Ascaris* infection, either albendazole administered at a fixed dose of 400 mg once or mebendazole administered at a fixed dose of 100 mg twice daily for 3 days is effective. A single fixed dose of 500 mg of mebendazole also may be effective, but it may be unsuitable for the treatment of other STH coinfections. As an alternative, pyrantel pamoate or ivermectin is effective. In a systematic review it was shown that single-dose oral albendazole, mebendazole, and pyrantel pamoate result in ascariasis cure rates of 88%, 95%, and 88%, respectively.¹⁹ The benzimidazoles and pyrantel pamoate are not approved for children younger than 2 years old, and printed statements caution against the use of these drugs in the younger age group. An examination of the use of benzimidazoles in children 12 to 24 months old concluded, however, that these agents are probably safe and should be used if the circumstances warrant it.⁵⁶ In such cases, the dose of albendazole in these young children should be reduced to 200 mg.³ The risk for treatment in this younger age group currently is undergoing more rigorous investigation because of mounting evidence that the growth and cognitive delay caused by STHs may be corrected with albendazole or mebendazole.^{29,30,28,56,61} These drugs have a potential for embryotoxicity, however, so judicious use in young children is warranted. The WHO is evaluating the use of benzimidazoles during pregnancy, particularly for use during the second and third trimesters.

In cases of intestinal obstruction, piperazine citrate may be effective because this drug paralyzes the myoneural junction of *Ascaris* and may result in relaxation of the matted bolus of worms. Piperazine citrate is frequently unavailable, however, and it is antagonistic to pyrantel pamoate, so these two drugs should not be administered together.

Management of intestinal obstruction or HPA often is surgical. For some patients, biliary decompression may be performed with endoscopic retrograde cholangiopancreatography.⁵²

Prognosis

The prognosis is excellent in most cases of ascariasis. In patients with obstruction or perforation, the prognosis depends entirely on the speed of recognition and therapy.

Prevention

Ascaris infection could be eliminated entirely through proper disposal of human excreta. As an isolated means of health improvement in the absence of economic development, this approach seldom is successful. Elimination of *Ascaris* from a community or a substantial reduction in the incidence of this infection usually occurs after general efforts in poverty reduction and improvements in the standard of living have been achieved. Periodic administration of community-wide therapy with anthelmintics has been effective in reducing worm burden as a short-term strategy. However, reinfection can occur within 6 months after treatment in areas of high transmission.³ Ultimately, of all the STH infections caused by the exquisite sensitivity of *A. lumbricoides* to benzimidazole anthelmintics and the concentration of *Ascaris* infections among children, ascariasis may offer the best chance of being eliminated through frequent and periodic MDA programs.

Trichuris trichiura

Trichuriasis has a prevalence of approximately 477 million cases worldwide,⁸ with the largest number of cases in South and Southeast Asia, and sub-Saharan Africa.^{2,59} Heavy infections, however, lead to colitis and sometimes dysentery. Light infections are often asymptomatic but may still result in deficits in cognition, however.^{7,22,78}

The infection is acquired by the ingestion of embryonated eggs acquired from the soil on hands or through contaminated food. The eggs hatch in the upper part of the small intestine, and the liberated larvae penetrate the villi. In contrast to the larvae of *Ascaris*, *Trichuris* larvae do not undergo extraintestinal migration but remain in situ for approximately 1 week, at which time they begin a progressive descent into the cecum and the colon. They mature there, and the attenuated anterior end of the adult worm embeds itself in the colonic mucosa. Creation of syncytial tunnels (derived from the columnar epithelium of the colon) is facilitated by the release of a parasite-derived, pore-forming protein.⁶⁸ The parasites derive their nourishment from these colonic mucosal tunnels. The entire cycle from the ingestion of embryonated ova to the development of sexually mature adults takes approximately 2 months. Persistence of the infection in a community depends on continual contamination of the soil with human feces.

Epidemiology

These parasites are found most commonly throughout the developing countries of the tropics and subtropics. The distribution of this worm often parallels that of *Ascaris*. In addition, as in the case of *Ascaris*, children with trichuriasis usually harbor greater numbers of worms than adults living under similar conditions.^{65,66} Consequently, children have greater morbidity from trichuriasis than adults do. The mechanistic basis of added worminess in children is unknown, although researchers have observed that for all of the soil-transmitted helminthiases, including trichuriasis, infections are aggregated, with a few children having particularly heavy infections. These heavily infected children seem to have a genetic or immunologic predisposition to *Trichuris* infection.^{65,66} Children also are the major source of *Trichuris* eggs in the environment; when the eggs are deposited in the soil, they become infective in approximately 1 month and remain viable for several months. They are killed by exposure to temperatures greater than 40°C within 1 hour. Freezing temperatures less than -8°C also destroy these eggs. Similar to ascarid eggs, *Trichuris* eggs are resistant to chemical disinfectants.

Pathophysiology

At the site of attachment, the adult worm elicits characteristic changes in the colonic mucosa, as noted earlier. Inflammatory cells also are found at these sites, but they do not seem to account entirely for the clinical resemblance of trichuriasis to some forms of inflammatory bowel disease.^{65,74} Similar to many other intestinal worms, *Trichuris* is expelled through the action of the host's immune system. This expulsion

results from a combined effect of antibody and lymphoid cells.⁸⁰ Regulation of *Trichuris* populations in the gut has been ascribed to a carefully orchestrated balance of host-derived cytokines.⁶⁹ Although anemia has been attributed to trichuriasis,⁷² the amount of blood loss caused by this parasite is much less than hookworm-associated blood loss and is insufficient to account for anemia.⁷³ One possibility is that *Trichuris*-induced anemia results from chronic inflammation, similar to the anemia of inflammatory bowel disease.^{65,66}

Clinical Manifestations

Two major disease syndromes are caused by heavy *Trichuris* infection during childhood.^{65,66} *Trichuris* dysentery syndrome (TDS) is associated with severe diarrhea with blood and mucus. It can also be associated with chronic iron-deficiency anemia,⁷⁰ although anemia should be considered first and foremost a hallmark of human hookworm infection. Children with TDS are anemic and frequently manifest growth retardation and failure to thrive.⁶⁷ Infants and toddlers with TDS are at risk for protracted tenesmus, which leads to rectal prolapse. *Trichuris* colitis is a more chronic manifestation of moderate to heavy infection that is characterized by a form of inflammatory bowel disease similar to what occurs in Crohn disease or ulcerative colitis. Children with this form of colitis also can have chronic malnutrition and short stature. Moderately and heavily infected (and possibly even lightly infected) children are at risk for having deficits in cognition and intellectual development.⁷⁸

Diagnosis and Differential Diagnosis

The diagnosis is established by identification of the characteristic barrel-shaped eggs through microscopic examination of stool. Clinically, heavily infected children with TDS may resemble children with amebic or bacillary dysentery. Children with *Trichuris* colitis may have signs and symptoms that resemble other forms of inflammatory bowel disease. The erythrocyte sedimentation rate is not elevated in children with *Trichuris* colitis, however. Among other diagnostic modalities, *Trichuris* colitis has been detected by Doppler ultrasonography,⁶⁴ whereas the presence of adult worms can also be seen on colonoscopy.⁷⁷

Treatment

In the past, when noxious or toxic drugs had to be used, only patients with heavy infection were treated. Currently, any patient with this infection can be treated by the administration of either albendazole, administered as a single fixed dose of 400 mg in MDA programs or on 3 successive days otherwise, or mebendazole, at 100 mg twice daily for 3 days.⁷⁵ A single dose of albendazole (400 mg) mebendazole (500 mg) also is used for MDA in some developing countries, although this practice is often not efficacious for trichuriasis. A systematic review revealed that cure rates after single-dose oral albendazole and mebendazole are only 28% and 36%, respectively.¹⁹ Studies indicate that the efficacy can be improved by using a double dose of albendazole or mebendazole given 8 hours apart.⁷⁶ A combination of albendazole and mebendazole has also been effective,⁷⁶ as is adding ivermectin to either albendazole or mebendazole.⁷¹ Because albendazole is frequently combined with ivermectin in MDA efforts to eliminate lymphatic filariasis in Africa, this practice could have important collateral benefits for trichuriasis. As alternatives, the drug oxantel pamoate is effective for the treatment of trichuriasis. In some countries, oxantel pamoate is formulated with pyrantel pamoate, and it has been reported that albendazole formulated with oxantel pamoate is highly effective in treating trichuriasis.⁶⁵ As noted earlier, the safety of the benzimidazoles in very young children has not been established, but this may not preclude its use in the practice of pediatrics.^{51,79}

Prevention

As in the case of other nematodes, sanitary disposal of excreta—but more important, improvement in the standard of living—tends to reduce the incidence of infection. Frequent mass treatments with mebendazole reduce the worm burden in a community.

Hookworms

Hookworm infection is one of the most important infections of adults and children in the developing world, with an estimated prevalence of

approximately 472 million cases.^{5,8,12} Hookworms are the predominant STH in sub-Saharan Africa⁹⁹ where they frequently cause coinfections with schistosomiasis and falciparum malaria.^{86,87,102} Hookworm infection is also widespread in Asia and Latin America.⁵⁹ Hookworms exert their pathogenic effect by causing intestinal blood loss, which leads to iron-deficiency anemia.⁹⁵ By considering the average daily blood loss induced by each worm, a moderate hookworm infection comprising 25 adult hookworms produces 1 mL of blood loss per day, often sufficient blood loss to rob a child of his or her daily iron requirement.⁹² Because loss of blood represents loss of erythrocytes and plasma, heavy infections also contribute to protein malnutrition.¹⁰⁰

Two major species of hookworms infect the human intestine: *Ancylostoma duodenale* and *Necator americanus*, although *N. americanus* is found more commonly worldwide (responsible for more than 80% of the global hookworm burden), especially in sub-Saharan Africa, Southeast Asia, and the Americas.³⁵ Two other zoonotic members of the genus *Ancylostoma*, the dog and cat hookworm *A. ceylanicum* and the dog hookworm *A. caninum*,¹⁰³ are much less frequent causes of intestinal pathology in humans.⁹⁴ *A. ceylanicum* causes hookworm infection in focal rural areas of the Asia-Pacific region,⁹⁷ whereas *A. caninum* is a rare cause of eosinophilic enteritis.⁹¹

The infection is acquired either by exposure of skin to moist soil infested with the larvae of these worms (*A. duodenale* and *N. americanus*) or by ingestion of the infective larvae (*A. duodenale* only). The most propitious circumstances for infection are shady areas and sandy or loamy soil. Infection is particularly likely to occur early in the morning, when the ground is moist with dew, or after a rainfall. After the larvae enter the host, they initiate a developmental program that continues until they enter the intestine.^{9,95} This process is coupled with the release of parasite-derived proteases and other virulence factors.¹⁰⁹ Larvae that enter through the skin are carried by the venous circulation to the right ventricle and there follow the route described for *Ascaris*, whereas larvae that are ingested may develop entirely within the gastrointestinal tract.

On reaching the small intestine, the larvae mature to adult worms, which become attached with their mouth parts to the intestinal mucosa. Eosinophilia begins during this phase of the infection. The adult worms sustain themselves by releasing hydrolytic enzymes that degrade the intestinal mucosa and then feed on cellular and connective tissue debris.⁹⁵ During this process, capillaries and arterioles are eroded and lacerated, with subsequent extravasation of blood. The adult worms also ingest hemoglobin in blood through the action of parasite gut brush border proteases.¹⁰⁷ Anticoagulants that block the activity of host factor Xa and VIIa/tissue factor facilitate blood flow and are responsible for continued bleeding from the original site after the worm has moved to a new one.⁹⁰

The entire cycle from penetration of the skin or ingestion of larvae to the development of mature worms usually takes 6 to 8 weeks. At that time, hookworm eggs appear in the feces. *A. duodenale* larvae also may undergo a period of developmental arrest within the human host that lasts weeks or months. Intestinal ancylostomiasis can occur up to 1 year (and possibly longer) after initial exposure to infective larvae has occurred.^{105,104} Investigators have conjectured that the reservoir of arrested *A. duodenale* larvae enters the mammary glands and breast milk.⁹⁴ This sequence of events may account for cases of infantile ancylostomiasis noted in Africa, India, and China.^{85,89,94} Humans are the major reservoir of these organisms, and this infection is maintained by continual contamination of soil by human feces.

Epidemiology

Although in ancient times these parasites had a worldwide distribution, they currently are most prevalent in areas of rural poverty in the tropics and subtropics. *N. americanus* is the predominant hookworm in the world, especially in the Western Hemisphere, most of Africa, China south of the Yangtze River, Southeast Asia and Indonesia, and certain islands of the Pacific. In Asia, *A. duodenale* predominates in many parts of the Indian subcontinent and focal areas of China north of the Yangtze River.⁹ *A. duodenale* also is a major parasite in Egypt and other parts of the Mediterranean region, Africa, and a few focal areas in South America, including Paraguay and northern Argentina. A small Central American focus also exists in southern Honduras and El Salvador, and

one exists among aboriginal populations in Australia. This differential distribution is not always absolute, and small numbers of either parasite can be present where the other predominates. Mixed infections with both species are common. *A. ceylanicum* occurs in focally endemic areas of southern Asia,⁹⁵ whereas the dog hookworm *A. caninum* has been described as a cause of human eosinophilic enteritis in Australia and possibly elsewhere.¹⁰⁰

Larvae survive in soil for 6 weeks. They are destroyed by drying, freezing temperatures, and heat greater than 45°C. Hookworm infection occurs in areas with high agricultural intensity and is not found frequently in urban areas, where *Ascaris* and *Trichuris* may predominate. Because shade and moisture are essential for survival at the infective larval stage, a not surprising finding is high rates of hookworm infection in families that harvest tea in India and Bangladesh, mulberry leaves (for the silkworm industry) in eastern China, sweet potatoes and corn in western China, coffee and bananas in Central and South America, and rubber in Africa.

Similar to other STHs, hookworm infections usually are aggregated such that most individuals harbor light worm burdens, whereas a substantial minority harbors moderate or heavy infections.^{95,105} Even after receiving specific anthelmintic chemotherapy, moderately and heavily infected individuals seem to be predisposed to the reacquisition of heavy infection.¹⁰⁵ A predisposition to hookworm infection may have a genetic or immunologic basis.

In contrast to the other STHs, high rates of hookworm infection occur in adults and children. In some regions, the age-associated prevalence and intensity increase linearly, with the heaviest infections occurring in older adult populations.⁹³ Hookworm coinfections with strongyloidiasis,⁸³ schistosomiasis,^{12,108} and malaria^{86,87} have been described and are believed to be common in low- and middle-income countries.

Pathophysiology

During the migratory phase of the infection, the larvae evoke an inflammatory response. Immune responses to the infection have been difficult to study in humans, but in an animal model a dog infected with *A. caninum* was rendered immune to challenge infection by receiving repeated dosing with the infective larvae. This observation provided a means of producing a live attenuated larval vaccine in the laboratory, but it is unsuitable for humans. An infective hookworm larval antigen known as ASP-2 has been identified as an immunodominant antigen linked to hookworm larval vaccines.^{82,84}

Host eosinophilia occurs as larvae enter the gut and mature into adult hookworms. Adult hookworms feed on human blood and have the capacity to lyse red blood cells and degrade host hemoglobin.¹⁰¹ The major source of injury to the host is loss of blood, with *A. duodenale* producing greater blood loss than *N. americanus*. Rarely, massive bleeding has been reported.¹⁰³ Iron-deficiency anemia results when iron loss exceeds the host's iron reserves. Because children and women of reproductive age generally have lower iron reserves than do other populations, they are at the highest risk for developing hookworm disease and anemia.⁹⁵ Systematic reviews have confirmed the association between anemia and hookworm infections in children and pregnant and nonpregnant adults.^{88,106} Long-standing moderate and heavy infections result in the characteristic features of severe iron deficiency. Loss of protein contributes further to malnutrition. Together, the iron deficiency and protein malnutrition result in impaired growth and physical fitness.^{24,29,30,28,95} In some cases, hypoproteinemia can be corrected by a high-protein diet without deworming the patient,¹⁰³ although the World Food Program and other international agencies now frequently incorporate deworming into their nutritional supplementation programs. In addition to the physical deficits noted earlier, hookworms may affect cognitive development because iron is important for the development of dopaminergic neurons and for the biosynthesis of some neurotransmitters.⁹⁵ An experimental human hookworm vaccine for *N. americanus* infections is under development; the vaccine targets key parasite enzymes involved in blood digestion and heme detoxification.¹²

Clinical Manifestations

Penetration by larvae causes "ground itch" or "dew itch," a type of pruritus that occurs after walking in the morning dew. These cutaneous

manifestations can occur on almost any part of the body. This phase of early infection is followed within days to weeks by pneumonitis, which typically is less pronounced than *Ascaris* pneumonitis.

The acute intestinal phase in heavy infections is characterized by abdominal pain, diarrhea, nausea, and anorexia.⁹⁴ Eosinophilia occurs approximately at the onset of the intestinal phase. Subsequently, well-nourished individuals with light infections have mild gastrointestinal symptoms, but no evidence of anemia or malnutrition. At the other extreme, children with moderate hookworm infections can show signs and symptoms of iron-deficiency anemia, whereas heavily infected children can have hemoglobin values of 2 g/dL and edema or anasarca caused by hypoproteinemia. Infants with severe ancylostomiasis can exhibit failure to thrive, profound pallor, and melena.^{85,89,94}

Deficits in physical and intellectual growth as a result of chronic hookworm infection in childhood have been reported since the early part of the 20th century.^{7,9,24,25,95} Some recovery has been described after “deworming,” although some deficits occurring in infancy may be irreversible.

Diagnosis and Differential Diagnosis

Hookworm pneumonitis resulting from the early migratory stages typically is nonspecific in its presentation and difficult to diagnose. Hookworm anemia is caused by blood loss; it must be distinguished from all other causes of intestinal loss of blood. In developing countries, where severe hookworm anemia is common, the probability of the occurrence of rarer causes of intestinal blood loss, such as Meckel diverticulum and polyps, is low. The opposite holds true for regions where hookworm infections are light or infrequent. In sub-Saharan Africa, the distribution of hookworm overlaps with other significant causes of so-called agricultural anemias, including malaria, schistosomiasis, malnutrition, and hemoglobin polymorphisms.¹⁷

The diagnosis is established by identifying the characteristic eggs by microscopic examination of stool. The eggs of *A. duodenale* and *N. americanus* cannot be distinguished from each other by morphologic criteria, but the worms can be differentiated by direct examination of the infective larvae or adults, or the polymerase chain reaction.⁴⁰ One must assume that it is one or the other species on the basis of the geographic origin of the patient. Although this decision is not of paramount importance, it does have some therapeutic implications, including the possibility that arrested larvae of *A. duodenale* would become reactivated and either repopulate the intestine at some point after treatment or enter breast milk during or after parturition. Hookworms have been detected visually by endoscopy.⁹⁸

Treatment

For *N. americanus* infection, the drug of choice is either albendazole, administered at a fixed dose of 400 mg, or mebendazole, given as 100 mg twice daily for 3 days. In settings of MDA for low-income countries, mebendazole is sometimes given as a single 500-mg dose. Pyrantel pamoate, given as a dose of 11 mg/kg, not to exceed 1 g, for 3 days is a suitable alternative drug. One meta-analysis and systematic review found that the efficacy of single-dose oral albendazole for hookworm infection was 72%, whereas single-dose mebendazole results in a cure rate of only 15% and pyrantel pamoate in a cure rate of 31%.¹⁹ In a systematic review single-dose mebendazole was shown not to improve hookworm anemia.⁸³ Therefore, albendazole should be considered the first-line treatment of hookworm infection. However, even single-dose albendazole frequently has failed to reduce hookworm burdens in some endemic settings.^{1,26,81} In areas endemic for ancylostomiasis, the health care provider should be aware of the potential of arrested tissue larvae to repopulate the intestine or enter breast milk and infect infants during the perinatal period. Iron supplementation and transfusion are occasional important adjunctive therapies for severe hookworm disease.

Prevention

As in all cases of STH infections, the sanitary control of the disposal of excreta represents an important public health control measure. Accomplishing effective sanitation in resource-poor settings has not been feasible in most of the developing world. The popular recommendation to wear shoes is naïve because *N. americanus* larvae also

enter through the upper extremities, torso, and legs and because *A. duodenale* also is orally infective. Studies to develop and test a first-generation recombinant hookworm vaccine are in progress.^{12,96} The human hookworm vaccine is in clinical trials in Brazil and Gabon. Unlike first-generation larval vaccines, this new vaccine targets adult blood-feeding hookworms.

Enterobius vermicularis

Pinworm infection (enterobiasis), or oxyuriasis (the older term), is one of the most frequent of all human helminth infections and one that is common in North America and Europe.¹²⁰ Some investigators believe that the overall prevalence of enterobiasis is declining in the United States, however. Most infected individuals are children, and the infection is found in all socioeconomic classes. It is acquired by the ingestion of infective eggs picked up on the perianal skin, in the air, or on bedclothes and underwear. Swallowed eggs, transmitted to the mouth by fingers or through inhalation, hatch in the duodenum, and the liberated larvae undergo additional maturational steps in the small intestine before reaching the cecum. There, the sexually mature worms copulate and proceed to the rectum and eventually to the perianal skin, where the gravid females lay eggs. The eggs become infective within 2 to 4 hours after deposition.

The entire cycle from ingestion of the egg to the egg-laying phase of the gravid female is 4 to 6 weeks. Rarely, a retrograde infection occurs in which eggs hatch on the anal mucosa and the larvae migrate up the bowel and mature to adult worms. Sexual transmission from oral-anal contact has also been reported.¹¹⁰ Although enterobiasis is a human infection, anthropoid apes can be infected experimentally.

Epidemiology

The infection is worldwide in distribution, and children are infected most frequently. Communal living, especially assembling in school gymnasias and living in crowded households, promotes transmission of the infection. Adults tend to be infected through their contact with children; parents and teachers are the most vulnerable. Orphanages and day care centers frequently are affected.¹²⁰

Pathophysiology

No intestinal reactions occur during the migratory phase, and because no tissue migration takes place, no eosinophilia occurs to the degree seen with some other nematodes. Occasionally, hypersensitive individuals may have a slight increase in eosinophils. The deposited ova induce pruritus on the perianal skin. No evidence indicates that some individuals are more susceptible than others to this infection.

Enterobius occasionally has been found in vermiform appendixes removed at surgery.¹¹² A causal relationship with appendicitis has not been established, but some evidence points to the possibility that this worm induces granuloma formation and may cause obstruction of this vestigial structure.^{111,113} When the adult gravid female migrates along the perineal skin into the vagina, it may cause vulvitis as a reaction to the eggs deposited in that region.¹¹⁵ Some investigators speculate that migrating pinworms may introduce bacteria into the lower urinary tract and result in urinary tract infection.¹¹⁹ *E. vermicularis* has also been reported from the fallopian tube and as a cause of infertility.¹²² Other aberrant infections, such as those causing hepatic granuloma and renal disease, occur more infrequently.^{114,118}

Clinical Manifestations

Pruritus is the most common symptom; its intensity varies from mild perianal itching to acute, intractable pain. Secondary cellulitis also may occur in severely pruritic cases.¹¹⁷ Perianal abscess has also been described.⁹⁶ Vaginal discharge and vulval itching are symptoms in the rare cases in which a worm has migrated into the vagina. Insomnia, restlessness, irritability, loss of appetite, loss of weight, and grinding of teeth all have been reported anecdotally in individuals with pinworm infection, but no evidence has shown that any of these symptoms is related causally to *Enterobius* infection. Enuresis also has been blamed on the pinworm, but one epidemiologic study failed to determine causality.¹²¹ An unusual form of eosinophilic ileocolitis resulting from massive infestation with many *E. vermicularis* larvae was described in

a homosexual man.¹¹⁶ Various clinical manifestations resulting from ectopic infections, including appendicitis and infertility, have been reported.^{112,122}

Diagnosis

E. vermicularis eggs are identified readily by low-power microscopic examination of transparent adhesive tape previously applied to the perianal skin and then affixed to a microscope slide.

Treatment

Single-dose therapy with mebendazole (100 mg), albendazole (400 mg), or pyrantel pamoate (11 mg/kg, not to exceed 1 g) is effective. With the current availability of these three highly effective drugs, the intensive laundering of underwear and bed clothing, recommended in the older literature, no longer is necessary. Treating all members of the household is advisable, however, because they all must be presumed to be infected. Repeat treatment in 2 or 3 weeks to destroy any adult worms that have hatched from the eggs swallowed at the time of initial therapy may be necessary. None of these drugs destroys the eggs.

One of the most important aspects of management of this infection is reassurance that in some areas its ubiquity virtually precludes effective eradication. Reinfection can be anticipated in any family infected with pinworms because of the high prevalence of this worm in the community. It also is important to reassure families that the presence of pinworms does not suggest poor hygienic standards in the family.

Strongyloides stercoralis and *Strongyloides fuelleborni kellyi*

Strongyloides stercoralis and *Strongyloides fuelleborni kellyi* are among the most virulent helminthic pathogens of humans, although human strongyloidiasis is believed to be less prevalent than *Ascaris* or hookworm, with some estimates indicating 30 to 100 million cases worldwide, but there is an urgent need to refine global disease burden estimates.¹⁴⁹ High rates of infection are found in Southeast Asia (especially rural Cambodia),¹⁴⁴ as well as selected areas of Africa and Latin America. Foci of strongyloidiasis are also believed to occur still in parts of the southern United States, including Appalachia.¹⁵³ *S. stercoralis* has the unusual ability to cause autoinfection, which can lead to hyperinfection and disseminated infection in immunocompromised hosts.^{106,110,113–117,119,125,126}

S. fuelleborni kellyi causes an aggressive infantile protein-losing enteropathy that leads to ascites and high mortality rates.^{123,124}

S. stercoralis infection is acquired by the exposure of skin to infective larvae in the soil, much as in the case of hookworm infection. Similar circumstances that promote the survival of hookworm larvae in soil (i.e., moisture, sandy or loamy soil, and shade) promote the survival of *Strongyloides*. Larvae penetrate skin, facilitated by a potent histolytic protease that they secrete.^{126,148} From the moment of penetration of the skin to the arrival of the worms in the intestine, the cycle commonly is thought to be similar to that of hookworms, although experimental evidence suggests that *S. stercoralis* also may explore routes of migration that bypass the lungs.¹⁵⁵ Within the intestine, the small adult worms do not attach to the mucosa as hookworms do but instead lie embedded in its folds. The cycle from penetration of skin to development of mature worms in the intestine is approximately 28 days.

No parasitic adult male worms exist to fertilize the eggs. Instead, the mature eggs may develop by parthenogenesis. In addition, in contrast to the eggs of other parasitic nematodes, these eggs usually are not found in feces but instead embryonate within the intestine and develop into larvae, which are deposited in soil with human stool. These so-called rhabditiform larvae must molt before they become infective.

This cycle has two variations. One permits the development of nonparasitic male and female adults in soil, which can maintain infestation of the soil for a certain period; this free-living phase sometimes is called the heterogonic life cycle. The second variation has much greater clinical relevance. Under certain conditions that are not well defined, the rhabditiform larvae molt to new infective larvae while they are still in the intestine. These new infective larvae can penetrate the intestine and set up a new cycle, commonly called autoinfection or the autoinfective cycle.¹³⁹ In this fashion, this nematode, in contrast to most other intestinal nematodes of humans, actually can increase in number without reinfection from the outside world. This phenomenon also is responsible for

persistence of this infection for decades in an untreated host.¹⁴¹ Some investigators think that low levels of autoinfection occur in most patients with strongyloidiasis, but this concept requires further investigation.

When host defenses are impaired, especially through use of high-dose corticosteroids (discussed later), *S. stercoralis* can undergo multiple rounds of autoinfection, leading to the production of thousands to hundreds of thousands of adult parasites in the intestine. This phenomenon is known as hyperinfection.^{128,134,140,151} One possible consequence of hyperinfection is disseminated infection, in which larval and adult worms are identified at extraintestinal sites.

S. fuelleborni kellyi larvae are passed to infants by ingestion in breast milk.^{123,127} Transmammary infection by nematode larvae is an extremely common route of transmission in nonhuman nematode infections²³; although not well studied, it probably also occurs commonly in humans.

Epidemiology

S. stercoralis infection has worldwide distribution, but it is most prevalent in tropical and subtropical regions.¹⁴⁹ The difficulty in diagnosing strongyloidiasis has hindered efforts to understand the global disease burden of this important illness more clearly. The highest prevalence is likely in Southeast Asia, but strongyloidiasis also is endemic in Brazil and Jamaica and presumably elsewhere in Latin America, as well as in sub-Saharan Africa.^{135,149,152} In North America, strongyloidiasis is focally endemic in some parts of Appalachia,^{130,153} and it is common in Southeast Asian immigrants.¹⁴² In one study, 76.6% of Kampuchean immigrants and 55.6% of Laotian immigrants were seropositive for *S. stercoralis* infection.¹⁴² Between 1991 and 2006 an estimated 347 deaths from strongyloidiasis occurred in the United States, mostly among older white men and those living in the southeastern states.¹³³ The seroprevalence in rural Appalachian Kentucky was estimated to be 1.9%.¹⁵³ Because of the possibility of autoinfection and, by extension, infection through contamination of skin by infested feces, strongyloidiasis is highly prevalent in mental hospitals, prisons, and homes for mentally disabled children. Dogs and anthropoid apes may serve as animal reservoir hosts for *S. stercoralis*. *S. fuelleborni kellyi* infection is endemic in Papua New Guinea and parts of sub-Saharan Africa.^{123,124,145}

Pathophysiology

During the migratory phase of the infection, the larvae of *S. stercoralis* evoke an inflammatory response associated with eosinophilic infiltration. The adult phase in the intestine, even in moderate infection, may be associated with an inflammatory reaction sufficient to be symptomatic. Some evidence suggests that *Strongyloides* induces a malabsorption syndrome, which has been treated effectively by deworming.^{130,150} It also has been noted, however, that the diarrhea associated with strongyloidiasis in young children occurs more frequently in those children with underlying malnutrition.¹³⁴ Young children with *S. stercoralis*-induced malabsorption experience stunted growth and failure to thrive.¹³⁰

The deficits in host defense that promote hyperinfection and disseminated strongyloidiasis are not well understood. Although cell-mediated immune deficits, such as those occurring in immunosuppression, organ transplantation, severe malnutrition, and cytotoxic chemotherapy for neoplasms and collagen vascular disease, are associated with this phenomenon, certain established deficits in cell-mediated immunity, such as those in HIV infection, do not trigger hyperinfection.¹³⁹ Researchers have suggested that patients receiving large doses of corticosteroids are particularly susceptible to hyperinfection because the corticosteroids themselves function as direct signals or ligands for the parasite to undergo autoinfection.¹³⁹ Patients with human T-cell lymphotropic virus type I seem to be at high risk for acquiring opportunistic strongyloidiasis,^{137,143} possibly because of a specific deficit in their effector IgE immune response.¹⁵² The pathogenesis of the marked protein-losing enteropathy that leads to ascites in the swollen belly syndrome of *S. fuelleborni kellyi* infection has not been established.

Clinical Manifestations

During the migratory phase of larval strongyloidiasis, patients may be susceptible to the development of pneumonitis associated with eosinophilia. Larval migration through the skin can result in larva currens. Although most patients harboring *S. stercoralis* in their intestine are

asymptomatic, patients with moderate or heavy infection classically have intense diarrhea productive of watery, mucous stool. Periods of alternating diarrhea and constipation may occur. Anorexia and cachexia, which lead to failure to thrive and other deficits in physical growth, are common features of pediatric strongyloidiasis.¹³⁰ Eosinophilia is also common, although among pediatric refugees this sign was not considered predictive of *S. stercoralis* infection.¹³⁶ Chronic strongyloidiasis has been linked to nephrotic syndrome.¹³²

In disseminated strongyloidiasis caused by the hyperinfective cycle, larvae may invade all tissues, including the central nervous system (CNS). Because larvae penetrate the intestine, they may carry with them enteric flora and cause sepsis or meningoencephalitis.¹²⁸ Although diarrhea is the most commonly recognized consequence of *Strongyloides* infection, the hyperinfective cycle has the greatest portent for immunosuppressed patients. Infants with *S. fuelleborni kellyi* infection may manifest the swollen belly syndrome, with marked abdominal ascites and pleural effusions that can be fatal. In older children *S. fuelleborni kellyi* infection can be associated with malnutrition.¹⁴⁵

Diagnosis and Differential Diagnosis

Strongyloides pneumonitis can resemble the clinical manifestations associated with the lung migration of other nematode parasites, such as *Ascaris* and hookworm. The differential diagnosis of diarrhea must include causes of chronic diarrheal disease. In some patients, eosinophilia is a presenting sign of strongyloidiasis, either in patients with diarrhea or even in asymptomatic immigrants from developing countries.

The diagnosis is established by identification of the characteristic larvae during microscopic examination of stool, which is not easy because rhabditiform larvae usually are not produced in abundance. Specific stool concentration techniques are available to increase the sensitivity of fecal examination, although they are not as effective as amplifying the heterogonic life cycle by the Baermann technique or by looking for characteristic larval tracks on nutrient agar plates.¹⁵⁶ The stool of all immunosuppressed individuals, including those given corticosteroids for any reason, who have ever been in a region where *Strongyloides* is found must be examined to rule out this infection. If routine stool examination results are negative, the stool should be processed as outlined earlier. In addition, examination of duodenal contents can be attempted by the string test (Enterotest). This examination divulges only the contents of the duodenum, however, and can miss the larvae in the lower part of the small intestine. An enzyme-linked immunosorbent assay (ELISA) for detection of *Strongyloides*-specific antibodies is available on a research basis, as is a polymerase chain reaction–based assay.^{40,142,152} The accuracy of five serologic assays including the different ELISA assays has been compared.¹²⁹

Children with the swollen belly syndrome from *S. fuelleborni kellyi* infection shed eggs rather than larvae in their feces. Large numbers of eggs are common findings in clinical cases.

Treatment

Previously, the drug of choice for *S. stercoralis* and *S. fuelleborni kellyi* infection was thiabendazole.¹³¹ The drug has high toxicity, however, which frequently includes nausea, vomiting, and vertigo and sometimes requires interruption of therapy. Rarely, it induces leukopenia, rash, and Stevens-Johnson syndrome. Because the drug is detoxified in the liver, its dose may have to be reduced for patients with liver failure. Another benzimidazole used with increasing frequency is albendazole 400 mg twice daily for 7 days. Studies have shown that ivermectin is equivalent to thiabendazole in terms of its efficacy, but ivermectin has a much better safety profile.¹²⁵ Similarly, single and double doses of oral ivermectin are more effective than a 7-day course of high-dose albendazole for patients with *S. stercoralis* chronic infection.¹⁵⁷

Ivermectin is considered the treatment of choice for strongyloidiasis. It is administered at a dose of 200 µg/kg per day for 2 days. Treatment with ivermectin gives a cure rate of 80%.^{143,147} The safety of the drug in young children (<15 kg) and pregnant women remains to be established. Because the mortality rate of patients with disseminated strongyloidiasis remains high despite specific anthelmintic therapy, a common practice is to treat with a prolonged course or with a repeat course of therapy. In addition, several case reports have now described

the use of veterinary parenteral formulations in patients too ill to take oral medications¹⁴⁷ or the use of ivermectin combined with albendazole.¹⁵⁰ Secondary bacterial complications, such as sepsis and meningitis, are common with disseminated strongyloidiasis, so judicious use of broad-spectrum antimicrobial agents frequently is indicated for this condition. As an additional supportive measure, patients who have hyperinfective strongyloidiasis and are receiving high-dose corticosteroid therapy will probably benefit from steroid taper. Patients with transplants and cyclosporine immunosuppression may benefit from some of the direct helminthotoxic properties of this compound.¹⁵⁴

Prognosis

The prognosis is excellent in patients who do not have disseminated infection and are treated promptly. Unrecognized disseminated infection can be lethal.

Prevention

Proper disposal of human excreta substantially reduces the prevalence of strongyloidiasis in any community. In closed institutions, where control of direct spread is not likely to be achieved, identification in addition to treatment of infected individuals is the only feasible control.¹³⁸ There have been calls to incorporate strongyloidiasis control more effectively in MDA activities for ascariasis, trichuriasis, and hookworm infection.¹⁴⁶

ABERRANT INFECTIONS WITH INTESTINAL NEMATODES

Toxocara canis and *Toxocara cati*

One of the most dramatic examples of an aberrant infection with an STH is visceral larva migrans and a related syndrome, ocular larva migrans, caused by infection with *Toxocara canis*. This species of roundworm causes intestinal infection in the dog, in which its cycle resembles that of *A. lumbricoides* in humans. Humans become infected by *Toxocara* through the ingestion of an embryonated egg, much as in human infection with *Ascaris*. Larvae hatch in the small intestine, penetrate the villi, and begin a migration that takes them through every organ and tissue of the body. Because they cannot mature, the larvae tend to migrate for months until they are overcome by the inflammatory reaction of the host and die. Although visceral larva migrans and ocular larva migrans are the most dramatic manifestations of toxocariasis, these are relatively rare conditions. In contrast, a covert form associated with eosinophilia together with either cognitive or pulmonary deficits may be widespread in the Western Hemisphere, including North America, as well as in Europe, Africa, and other regions. There are no published global disease burden estimates.

Although larvae of other toxocarids such as *Toxocara cati* and *Toxascaris leonina* have been suggested as possible causes of visceral larva migrans, they may be less important as zoonotic pathogens in humans. However, the more recently noted association between toxocariasis and toxoplasmosis seroprevalence has reopened the possibility that *T. cati* may also be an important environmental cause of *Toxocara* egg contamination in the environment.¹⁴⁶

Because population-based serologic testing is limited to only a handful of research studies,^{21,159,171,181,182} the prevalence of toxocariasis in North America and elsewhere may be underestimated. According to some investigators, *T. canis* infection may have replaced *E. vermicularis* as the most common helminth parasite in the United States.¹⁸ A critical question regarding toxocariasis in North America and elsewhere is the potential contribution of the covert form of this disease to cognitive and learning deficits among socioeconomically disadvantaged children.¹⁷⁴

Epidemiology

The prevalence of toxocariasis is difficult to assess because of the failure of establishing the diagnosis in many cases. The disease has been reported from many parts of the world, including temperate climates, and one can assume that it is found wherever humans and dogs coexist. High prevalence rates of the infection have been reported from Brazil, Africa, Eastern Europe, and the United States and Mexico^{14,18,10,21,165}; toxocariasis may represent one of the most common helminth infections worldwide.¹⁸

Young children often come into contact with *Toxocara* eggs while playing in sandboxes and on playgrounds that were contaminated by stray dogs or cats or a family pet.^{173,176} The level of contamination of public areas also is difficult to ascertain. In several studies, ova were present in 5% to 25% of soil samples obtained, and surveys of dogs in urban communities have shown the occurrence of frequent infections, particularly in puppies, which are infected almost universally with *T. canis* (canine infection occurs transplacentally).^{168,169}

Subsequent dissemination of *Toxocara* eggs in the environment probably is aided by migrating earthworms and other soil invertebrates.¹⁶⁴ The seroprevalence of toxocariasis in the United States is high, and the parasite should be considered an emerging pathogen in some poor rural and urban areas. In some groups of socioeconomically disadvantaged black children, the seroprevalence is 30%,^{172,180} with even higher rates occurring among US inner-city Hispanic children.¹⁸² In the United States, the disease is linked to being poor and of African American or Hispanic ethnicity.^{18,10,166,188} It has been estimated that up to 2.8 million African Americans have toxocariasis, so this disease represents a major but neglected health disparity.¹⁰ Toxocariasis is endemic to Puerto Rico. Major risk factors for acquiring toxocariasis include having a litter of puppies in the home and the habit of geophagia.¹⁷⁷ The latter risk factor probably accounts for the observed association between toxocariasis and elevated lead levels.¹⁷⁷ In the poorest areas of the United States, including impoverished rural areas and in degraded urban environments, it is possible that *Toxocara* eggs are ubiquitous, and this accounts for the high seroprevalence of this infection among vulnerable populations. In Ireland, the prevalence of ophthalmologist-diagnosed ocular toxocariasis is 9.7 per 100,000, whereas in the United States it was determined that 68 patients were newly diagnosed with ocular toxocariasis between September 2009 and September 2010.^{163,173}

The presence of a positive skin test result for toxocariasis is associated with poliomyelitis statistically.¹⁸⁹ No direct causal relationship exists; possibly, the circumstances leading to ingestion of *Toxocara* ova also are conducive to ingestion of poliomyelitis virus. *Toxocara* and *Toxoplasma* coinfections have also been noted; possibly these are from *T. cati* infection reflecting concurrent exposure from cats.¹⁷⁵ Several provocative studies have linked *Toxocara* exposure to neurologic and pulmonary disease. For example, seizures, cognitive deficits, pulmonary dysfunction, and asthma are correlated with seropositivity for *Toxocara* antibodies, but a causal relationship has not been established.^{18,159,186,187,185} Some investigators have postulated that toxocariasis may be an important cause of asthma, idiopathic seizures, and cognitive delays in young children.^{18,170,173} Given the link to poverty, important questions need to be addressed regarding *Toxocara* eggs as an environmental cause of asthma and developmental delays among socioeconomically disadvantaged children.¹⁷⁴

Pathophysiology

The entire infection is restricted to the migratory phase and bears some clinical resemblance to the symptoms found during the early phases of *A. lumbricoides* infection. Symptoms are protean and depend on which organ or tissue is infected. For unknown reasons, visceral migration through the liver, lungs, and brain occurs more commonly in toddlers and children younger than 5 years old, whereas older children are more likely to exhibit only ocular involvement.^{173,176} Epidemiologic evidence suggests that this infection produces two distinct syndromes, visceral and ocular, because involvement of one tends to occur in the absence of the other.¹⁷¹ Visceral migration elicits eosinophilic granuloma formation in the target organs and leads to hepatitis, pneumonitis, or cerebritis. Larval migration in the retina results in ocular larva migrans, which includes granuloma formation in the retina.^{160,167,183} The lesion can resemble retinoblastoma so that it often is confused with it. Endophthalmitis¹⁶⁷ or papillitis¹⁶⁴ also may develop. Invasion of other organs and tissues induces granuloma formation. The third and perhaps most common pathophysiologic process results in a covert form of the disease linked to larval migrations but without ocular or obvious visceral findings. These individuals exhibit positive *Toxocara* antibody titers often accompanied by eosinophilia. The covert form may be linked to pulmonary and neurologic deficits, including lung dysfunction and cognitive delays, respectively. The factors responsible for whether children develop

visceral or ocular larval migrans versus the covert form of the disease are not known.

Clinical Manifestations

Most patients infected with *T. canis* are thought to be asymptomatic. Some of these individuals have isolated findings, including eosinophilia, or wheezing and asthma. The term *covert toxocariasis* is used by some investigators to describe these patients, who often are identified by their circulating anti-*T. canis* antibody titers. An association between asthma and covert toxocariasis has been well described in Europe, but as yet this association is unproven in North America.¹⁸² Potentially, this association would represent an important avenue for investigation, given the high prevalence rates among African American and Hispanic children who live in poverty in the United States and are considered at high risk for asthma.¹⁸

Visceral larva migrans, the extreme form of toxocariasis, typically occurs in a toddler with the symptoms and signs of a multisystemic disease. It is associated with fever, hepatosplenomegaly, lung infiltrates accompanied by wheezing, a high degree of eosinophilia (approaching 80%), and elevated immunoglobulin levels, particularly of the IgM class.^{170,173,176,177} Seizures and neuropsychiatric disturbances also are common. In one case report, the child's major neurologic manifestation was static encephalopathy.¹⁷⁰

In contrast, ocular larva migrans is characterized by a unilateral vision deficit and, sometimes, strabismus. Ophthalmologic examination frequently reveals one or more posterior poles or peripheral pole granulomas.^{167,176,183} More global eye inflammation also can occur (discussed earlier). Children with ocular involvement usually have few, if any, systemic manifestations. Often, no laboratory abnormalities are detected.

In covert toxocariasis, the individual is often asymptomatic, except some persons develop wheezing or other evidence of lung dysfunction. Alternatively, they may exhibit cognitive deficits or epilepsy. Both the pulmonary and neurologic sequelae of covert toxocariasis may or may not be accompanied by eosinophilia. The extent and clinical importance of covert toxocariasis still require further clinical investigations.

Diagnosis and Differential Diagnosis

Visceral larva migrans must be distinguished from the migratory phase of the other nematode infections. Because of hepatosplenomegaly and hypereosinophilia, eosinophilic leukemia occasionally has been suspected, but it can be ruled out readily by examining bone marrow.

T. canis larvae can be identified in tissues in liver biopsy specimens, but the diagnostic yield is low. One must resort to indirect means and be aware that a multisystemic disease with elevated IgM and hypereosinophilia fits the diagnostic criteria. An ELISA available at the Centers for Disease Control and Prevention is highly specific and diagnostic.^{176,181,180} However, the exact interpretation of being seropositive to *T. canis* is considered controversial; some investigators are of the opinion that this finding reflects previous exposure, whereas others believe it indicates the presence of actively migrating larvae. Efforts to improve the existing ELISA by substituting antigens prepared from living larvae with recombinant protein-based reagents (to make testing kits more widely available) are in progress.^{158,190}

Ocular larva migrans usually is diagnosed by an experienced ophthalmologist who recognizes the characteristic granulomas and larval tracks on retinal examination. Presumably because of minimal antigen presentation by a few migrating larvae in the eye, often no measurable immune response occurs in this condition. For this reason, ELISA frequently is unreliable for establishing the diagnosis of ocular larva migrans.^{172,176,177,181,180}

The full clinical spectrum of the third form of toxocariasis, covert toxocariasis, is still under active investigation. There is no single case definition of covert toxocariasis, but it has been loosely defined as exposure to *Toxocara* eggs and larval migrations that are either asymptomatic or with physical findings confined to evidence of pulmonary or neurologic on further testing, together with a positive ELISA result. Covert toxocariasis generally requires a high index of suspicion on the part of the clinician; most cases go undiagnosed.

Treatment

Traditionally, treatment of visceral larva migrans was primarily symptomatic, especially because much of the morbidity is associated with immunopathologic responses against dying parasites. In the 1960s, thiabendazole and diethylcarbamazine were determined to be effective against migrating larvae.¹⁷⁹ Since then, newer agents of the benzimidazole class have been claimed to be equally effective but associated with fewer drug toxicities.¹⁷³ In a comparative study with thiabendazole, albendazole 10 mg/kg per day in two divided doses for 5 days was shown to be well tolerated and less toxic.¹⁸⁴ Another benzimidazole, mebendazole, also may be effective when given in doses high enough to achieve significant extraintestinal levels.¹⁶¹ Albendazole 400 mg twice daily for 5 days is the treatment of choice.¹⁷⁸ As in almost all drug treatments for parasitic infections using albendazole this indication is not approved by the US Food and Drug Administration. Although anecdotal experience with albendazole and mebendazole overseas suggests that these drugs are safe in children,¹⁶² the large doses required for the treatment of larva migrans may be associated with hepatic and other toxicities (including embryotoxicities), and they have not been approved for this purpose.

Treatment of ocular larva migrans often requires surgical management, particularly in cases associated with tractional retinal detachment.^{167,183} Specific anthelmintic adjunctive chemotherapy seems to be beneficial in some cases.^{168,173,183}

Prognosis

Except for patients in whom blindness develops as a consequence of retinal damage and a rare fatal case resulting from the intensity of the acute clinical reaction, most patients recover. The recovery phase may be slow, however, and may take 2 years.

Prevention

Theoretically, the disease can be prevented by elimination of dog and cat feces from the human environment, but in practice that is no less difficult to achieve than control of human excrement disposal. Animal control for stray dogs and cats, especially in degraded urban environments, is also needed.

OTHER ABERRANT INFECTIONS WITH INTESTINAL NEMATODES

Baylisascaris procyonis, a parasite of raccoons, also can cause visceral larva migrans, as well as an emerging eosinophilic meningitis.¹⁹⁸ *Baylisascaris* infection occurs when humans accidentally ingest parasite eggs that are shed in barn lofts and attics accessible to raccoons.^{177,196,197,200,202} In at least one reported human case, the infection was fatal in an infant.²⁰⁰ Similar to *Toxocara* infection, *Baylisascaris* larvae within aberrant hosts cannot complete their cycle and continue their aimless migration through the tissues of these hosts. Baylisascariasis is probably more severe because of the propensity of the larval stages of the parasite to invade the CNS, however, along with the continued growth of the larvae during migration resulting in greater mechanical damage.^{196,197} The lesions caused by the larvae are eosinophilic granulomas, which tend to be concentrated in the CNS and result in eosinophilic meningitis. The disease is characterized by a severe eosinophilic pleocytosis in the cerebrospinal fluid and nonspecific diffuse white matter lesions seen on magnetic resonance imaging.¹⁹⁸ Neither the frequency nor the range of severity of this infection in humans is known. Most human cases have been diagnosed at autopsy. Because baylisascariasis is so uncommon, no studies are available to evaluate different anthelmintic chemotherapy regimens systematically. Some clinicians have recommended prolonged treatments with high doses of albendazole.^{196,197} Given the potential severity of infection, some investigators propose administering postexposure prophylaxis after intimate contact with raccoon feces or soil contaminated with raccoon feces (albendazole 25 mg/kg per day orally for 20 days) as soon as possible after exposure and up to 3 days after possible infection.¹⁷⁸ Prolonged albendazole treatment requires monitoring of blood cell counts and liver function.

Other, less severe aberrant infections of importance to humans are those caused by the dog hookworm, primarily *Ancylostoma braziliense*, but possibly also *Uncinaria stenocephala*.^{94,196,199,210} Infection with the

larvae of *A. braziliense* and *U. stenocephala* cannot be completed, and larvae remain viable and migrate in the skin (usually between the epidermis and dermis); hence the terms *cutaneous larva migrans* and *creeping eruption* are used. In North America, cutaneous larva migrans is common along the Gulf Coast and along the Atlantic seaboard.⁹⁵ It also is common in the Caribbean. Failure of these zoonotic hookworms to complete entry through the human skin may reflect differences in the hydrolytic enzymes released.¹⁹⁹ Infection is acquired in the same fashion as that of the human hookworms. Children who expose their whole bodies to contaminated soil may be infected at any site. Adults are most likely to have infection in the lower extremities, but plumbers in the tropics, who often must crawl beneath houses, acquire infection on the elbows and knees.

The interval from exposure to appearance of the first symptoms is approximately 2 weeks; papules 2 mm in diameter then begin to appear on the skin. Behind them usually are seriginous, erythematous, intracutaneous tunnels. The entire area itches intensely. If left untreated, cutaneous larva migrans tends to last 2 months. Albendazole, 400 mg daily for 3 days, or ivermectin, 200 µg/kg daily for 1 to 2 days, is effective treatment when administered orally. Topical therapy with a 15% aqueous suspension of thiabendazole was successful in one reported series. Forty-seven of 50 patients achieved permanent cure in 2 weeks, and 2 more patients were cured after a third week of treatment.²¹³ Placebo-treated patients were used as controls in this study. In contrast to skin penetration of zoonotic hookworms, oral ingestion of the dog hookworm *A. caninum* results in an eosinophilic enteritis syndrome (see the earlier discussion of hookworm infection).

Rarer aberrant infections include those caused by various species of *Trichostrongylus*, *Oesophagostomum*, *Angiostrongylus*, *Capillaria*, and *Anisakis*. *Trichostrongylus* is a common parasite of many mammals, and it has been found in the small intestine of humans, mainly in Asia, Africa, and Australia. Ingestion of larvae leads to the development of adult worms in the small intestine. Whether this development results in any disease remains a moot point because infections tend to be mild and usually are associated with other helminth infections.¹⁹⁷ *Oesophagostomum bifurcum* is a common nematode of subhuman primates in Africa and has been reported to be a common intestinal nematode that causes nodular disease of the intestines in humans living in West Africa.^{204,207} Human esophagostomiasis has been treated successfully with pyrantel pamoate.²⁰⁴

Land snails and slugs serve as intermediate hosts for *Angiostrongylus* spp. *Angiostrongylus cantonensis* is a cause of eosinophilic meningitis (neuroangiostrongyliasis) throughout eastern Asia and Hawaii.^{193,203,208,209} *A. cantonensis* has also emerged in the mainland United States, especially on the Gulf Coast after importation of infected rats and African land snails on container ships.¹⁹⁵ *Angiostrongylus costaricensis* is a cause of mesenteric arteritis and abdominal pain in Central and South America and in Latin American immigrants to the United States.²⁰¹ The rat serves as the natural host of these parasites, which live either in the lung (*A. cantonensis*) or in mesenteric arteries (*A. costaricensis*). The rat eats the infected mollusks and ingests the larvae, which migrate to their final destination. An incomplete infection develops in individuals who ingest either the mollusks or food contaminated by the mollusks. *A. cantonensis* infection usually is limited to the CNS and is manifested as eosinophilic meningitis.^{193,203,208,209}

Signs and symptoms of neuroangiostrongyliasis include meningismus, severe headache, paresthesias, and, less commonly, cranial nerve palsies. No specific treatment is available (although anthelmintics are effective in some experimental animal models¹⁹³), but the disease is self-limited and lasts no longer than 2 weeks. Symptomatic relief has been reported with the use of prednisone. Some investigators have reported success in treating neuroangiostrongyliasis with albendazole and prednisone, together with repeated spinal taps to decrease intracranial pressure.¹⁹⁸ However, the treatment of *A. canontensis* infection is considered controversial and “varies across endemic areas” because no anthelmintic has proven to be effective.¹⁷⁸ In contrast, *A. costaricensis* infection typically is manifested as abdominal or right iliac fossa pain, fever, and eosinophilia. In children with this condition, appendicitis or Meckel diverticulum may be diagnosed.²⁰¹ High doses of mebendazole have been tried as therapy for this condition, as well as albendazole.

Capillaria philippinensis is a common parasite of water fowl in the Philippines.¹⁹² The mode of transmission of this parasite to humans is unknown, but human cases have been reported in which 40,000 adult worms were found embedded in the crypts of the small intestine. *C. philippinensis*, similar to *S. stercoralis*, can undergo autoinfection and hyperinfection in humans.¹⁹² No associated inflammatory reaction occurs, but flattening of villi, loss of epithelial surface area, and severe malabsorption have been reported.^{192,194,212} In a series of 1000 cases of *C. philippinensis* infection, a mortality rate of 10% was reported.¹⁹⁴ Thiabendazole may be effective in shortening the course of the infection,²¹² although albendazole has become the treatment of choice more recently.¹⁹² At least one recommended regimen of albendazole includes 400 mg daily for 10 days, whereas for mebendazole 200 mg twice a day for 20 days is administered.¹⁷⁸ Neither regimen is approved by the US Food and Drug Administration. Another member of the genus, *Capillaria hepatica*, a rare zoonosis of humans, has been known to disseminate to the lungs, liver, and other viscera.²⁰⁶

Anisakis spp. are nematode parasites of marine mammals, with fish being intermediate hosts. When the infective larvae of the parasite are ingested as a result of eating raw or poorly cooked fish, they may become embedded in the gastric mucosa and cause eosinophilic granuloma.^{76,157,171,177,181,185} In adults, the infection may resemble carcinoma of the stomach clinically and radiographically. Human anisakiasis occurs frequently in Japan, where raw marine fish are eaten commonly, and in Holland, where lightly pickled herring is considered a delicacy.

FILARIAL PARASITES

Except for rare instances of zoonotic *Brugia* infection, the filarial worms parasitizing humans affect people within the geographic area almost entirely limited to the developing world, especially sub-Saharan Africa, India, and Southeast Asia. Although accurate data are lacking, approximately 115 million people are infected with lymphatic filariasis, more than 40 million of whom are symptomatic, and 17 million are infected with onchocerciasis.^{8,217} The various human parasites in this category have certain characteristics in common. They all are spread by vectors, and the adults invade and occupy the lymphatics, skin, connective tissue, or blood. They produce live embryos called microfilariae that enter the bloodstream or skin, where they can survive for months or years without further development. The range of disease caused by these worms is wide; some produce no symptoms, whereas others can be responsible for severe clinical disorders.

The life cycles of the filarial worms are similar in that infections are acquired through an insect bite, during which transmission is effected by introduction of infective larvae onto the skin of the host from the mouth parts of the insect. The larvae enter the wound in the skin and make their way to the respective tissue, where they mature into adult worms. The adults mate and produce live microfilariae, which, in lymphatic filariasis, migrate to the blood through the walls of the lymphatics or through the thoracic duct. To complete the life cycle, the microfilariae are ingested by blood-sucking insects, in which they undergo metamorphosis through two larval stages until they reach the third, infective stage. The interval from the infective bite to the appearance of microfilariae in the blood of the host can be 6 to 12 months.

MDA with ivermectin alone (for onchocerciasis), or ivermectin together with albendazole (for lymphatic filariasis), or diethylcarbamazine with albendazole (also for lymphatic filariasis) can reduce the microfilarial load of human populations living in endemic regions.²¹⁸

For onchocerciasis, reductions in microfilarial loads lead to reductions in chronic morbidity, with marked improvement in the serious skin manifestations of the infection and the prevention of blindness. MDA using ivermectin can result in the elimination of onchocerciasis. Such programs of MDA for onchocerciasis are in progress in 19 sub-Saharan African countries, under the auspices of the WHO in collaboration with its African Programme for Onchocerciasis Control (APOC),²²¹ whereas in the Western Hemisphere onchocerciasis is close to being eliminated in 5 countries through the activities of the Onchocerciasis Elimination Program for the Americas (OEPA), leaving only foci of infection among indigenous populations living near the border of Brazil and Venezuela.²²²

For lymphatic filariasis, widespread implementation of MDA one day may reduce transmission to the point of elimination, and a target for the year 2020 has been set for elimination. Through the WHO and the Global Programme to Eliminate Lymphatic Filariasis, such programs are currently under way in many countries in Asia, sub-Saharan Africa, and in Haiti.²²⁰ For example, in Egypt, five rounds of mass drug distribution already may have effectively eliminated transmission.²¹⁹ Because the major manifestations of both lymphatic filariasis and onchocerciasis occur mainly in adults rather than children, both topics are treated only briefly here. An important exception is the emergence of a “nodding syndrome” affecting children in some of the onchocerciasis-endemic areas of South Sudan and Uganda, and possibly elsewhere in East Africa.

Lymphatic Filariasis: *Wuchereria Bancrofti* and *Brugia* Species

Epidemiology

Wuchereria bancrofti is prevalent primarily between the Tropic of Cancer and the Tropic of Capricorn but also is encountered north of the Tropic of Cancer in Africa. An estimated 115 million infections exist in 80 countries worldwide, with approximately one-half of the infected individuals living in sub-Saharan Africa.^{217,219,228} In each of its geographic locales, it has a specific anopheline, culicine, or aedine mosquito vector. In the Caribbean area, South America, Asia, East and West Africa, and Papua New Guinea, the microfilariae of this worm exhibit nocturnal periodicity; in the South Pacific, their periodicity is diurnal. *W. bancrofti* has no animal hosts.

Brugia malayi occurs in India, Malaysia, and other parts of Southeast Asia. Some strains of *B. malayi* are associated with animal reservoirs, as are certain other members of the genus *Brugia*, such as *Brugia timori*. In the United States, zoonotic *Brugia* infections caused by *Brugia beaveri* and *Brugia lepori* may infect humans but cannot develop patent infections.^{216,226,227}

Pathophysiology

The pathology of lymphatic filariasis is caused principally by the adult-stage parasite, the host response, and an unusual type of bacterial coinfection of tissues (resulting from helminth endosymbiotic bacteria of the genus *Wolbachia*), which together produce compromised lymphatic function. In children the adult worms initially induce lymphatic dilation that over time results in lymphatic dysfunction, lymphedema, and further sequelae, although the exact mechanisms responsible for these processes are still under investigation. The consequent inflammation, in addition to that caused by host responses to dying parasites, damages the delicate lymphatic vessels further and compromises lymphatic function further. When such processes occur in the lymphatic vessels of the scrotum, hydrocele develops. As tissue pathology progresses, some patients develop severe morbidity from elephantiasis. Microfilaremia often is “asymptomatic” but frequently is associated with immune complex nephritis; more rarely, the microfilariae can be the target of immunologic hyper-responsiveness and result in a severe “tropical pulmonary eosinophilia” syndrome.²²⁴

Clinical Manifestations

Asymptomatic microfilaremia often develops in children living in endemic areas. By using highly sensitive diagnostic tests, including antigen detection and ultrasound (“dancing filarial sign”), one-third of children living in endemic areas can be seen to be infected before age 5 years. Damage to the lymphatics of these young children frequently is subclinical, however.²²⁹ With repeated exposure, these children begin to have episodes of acute adenolymphangitis, sometimes associated with fever and lymphangitis. These “filarial fevers” may reflect either an inflammatory response to dying parasites (with “retrograde” lymphangitis) or *Wolbachia* endosymbiotic bacterial coinfection.²¹⁵ Progression to lymphedema of the upper and lower extremities, the most common sequela of chronic lymphatic filariasis, is an uncommon occurrence in children until after the age of puberty. Arthritis has also been noted as an occult manifestation of lymphatic filariasis in India.²²³ Benign lymphedema has been described in a few patients in the United States with zoonotic *Brugia* infection.^{216,227} Chronic, recurrent eosinophilic

pneumonitis associated with wheezing, cough, chest pain, pulmonary infiltrations, and hypereosinophilia (tropical pulmonary eosinophilia) is an IgE-mediated hypersensitivity reaction to microfilariae trapped in the lungs and, if left untreated, leads to debilitating interstitial pneumonitis.²²⁴

Diagnosis and Differential Diagnosis

The differential diagnosis of lymphatic obstruction in children should rule out other, more likely conditions before focusing on filariasis. In older children and adults, familial lymphedema (Milroy disease) can mimic filariasis.

In endemic regions, lymphatic filariasis typically is diagnosed on the basis of appropriate clinical findings in a region with known endemicity for the disease. In young children living in endemic areas, however, early infection is largely subclinical.²²⁹ A definitive diagnosis of lymphatic filariasis still relies on detecting adult parasites in the lymphatics through ultrasonography or by recovering microfilariae from the blood. In the past, in view of the circadian periodicity of the appearance of numerous microfilariae in blood, a specimen was collected at the appropriate time, in many regions of the world between 10 PM and 2 AM, for microscopic examination by a staining or concentration technique. Increasingly, an immunochromatographic card test that measures specific filarial antigen is being used, especially in amicrofilaricemic individuals.²¹⁵

Treatment

New agents or drug regimens are needed that would be more effective against the adult filarial worm (a “macrofilaricide”) and at the same time elicit minimal immunopathologic damage. Currently, the major drugs used are especially effective against microfilariae. Diethylcarbamazine is the treatment of choice and typically is given in a 12-day course (6 mg/kg per day in three doses) for a total dose of 72 mg/kg. In the United States, for patients with microfilariae in the blood, it is common practice to administer first small doses of 1 to 2 mg/kg (maximum of 50 to 100 mg) before beginning this regimen. One regimen includes beginning 50 mg on day 1, followed by 50 mg three times per day on day 2, 100 mg three times per day on day 3, and 6 mg/kg per day in three doses on days 4 to 14. More recently, a single dose of 6 mg/kg has been recognized to produce a similar therapeutic result (presumably following the test doses as just outlined).²¹⁵ Diethylcarbamazine is available under an investigational new drug protocol from the Centers for Disease Control and Prevention (CDC Drug Service: 404-639-3670 [evenings, weekends, or holidays: 770-488-7100]).

Side effects of specific antifilarial therapy include allergic and febrile reactions that are caused by the inflammatory response to dying microfilariae, rather than by the drug itself, and that occur primarily in patients with high levels of circulating microfilariae. These systemic manifestations can be treated symptomatically with antihistamines or corticosteroids. Some of the allergic manifestations also may be avoided by administering diethylcarbamazine in a graded, stepwise manner. For patients with *Loa loa* coinfections, the presence of microfilariae presents a particular problem because high levels of microfilaremia can lead to encephalopathy after treatment with antiparasitic drugs. Diethylcarbamazine also is the treatment of choice for tropical pulmonary eosinophilia, a syndrome caused by circulating microfilariae. Ivermectin also may have a role in the medical treatment of lymphatic filariasis because it is very effective in clearing circulating microfilariae.²²⁵ Albendazole, in high doses, is effective in killing adult worms and, in lower doses, inhibits microfilarial production, but it is not registered for use in lymphatic filariasis in the United States.²¹⁹

The difficulty in management of filariasis by drugs is that late symptoms, such as elephantiasis, do not abate. The main usefulness of chemotherapy is in cases recognized early, before the anatomic abnormalities develop. Hydrocele can be treated surgically. Of critical importance to the management of lymphedema and elephantiasis are attention to hygiene, wearing shoes to prevent injury, and reduction of lymphostasis with exercise and elevation of the lower extremity.

The more recent discovery that *W. bancrofti* harbors bacterial endosymbionts has led to efforts to use tetracycline and related antimicrobial agents as part of the therapeutic regimen for lymphatic

filariasis.²²⁷ The therapeutic use of such regimens is under active investigation. The Centers for Disease Control and Prevention (see earlier) and the Clinical Center of the National Institutes of Health have extensive experience and expertise in the management and treatment of human filarial infections, including *W. bancrofti*, *L. loa*, and *Onchocerca volvulus* infections.

Prevention

Prevention in the past depended principally on vector control, which was successful in some settings and unsatisfactory in others, primarily because of the difficulty in developing effective insecticides that also would be nontoxic to the rest of the environment. Successful experience in China has shown that large-scale chemoprophylaxis approaches to prevention are possible in endemic countries. Currently, through the Global Programme to Eliminate Lymphatic Filariasis, the international community is directing a large-scale lymphatic filariasis control campaign on this principle. Typically, this control is being accomplished through a single-dose combination of albendazole 400 mg with either ivermectin 200 µg/kg or diethylcarbamazine 6 mg/kg. On this basis, lymphatic filariasis has been eliminated in more than 20 countries, and long-term targets for the global elimination of this infection have been proposed.²¹⁷⁻²¹⁹ The finding of extensive subclinical infection among children living in endemic regions highlights the importance of targeting this group for MDA, as well as adults.²²⁹

Loa Loa

L. loa infection is limited to a focal area of western and central Africa and is spread by *Chrysops* flies. Periodicity in *L. loa* microfilariae is diurnal. The parasite elicits numerous allergic inflammatory responses that are most evident in expatriates.^{230,231} Infection leads to high eosinophilia and recurrent angioedema, which when localized develop into painful, pruritic, subcutaneous swellings on the extremities and the face known as Calabar swellings. Rarely, some cases of lymphatic obstruction of the lower extremities and hydroceles have been reported.

The most dramatic manifestation of this infection is the occasional appearance of a migrating *L. loa* adult under the conjunctiva of the eye. It does not damage the eye and can be removed surgically. Because of the genuine risk of encephalopathy, treatment with diethylcarbamazine, as indicated earlier, effectively destroys the adults, but reactions may be more intense than in the treatment of *Wuchereria* and *Brugia* infections. Diethylcarbamazine should be administered in a gradual, stepwise manner as described earlier, particularly in patients with high levels of circulating microfilariae. The recommended dose is higher than that used for lymphatic filariasis (9 mg/kg per day in three doses for 12 days). Coadministration of corticosteroids often is required during treatment. Encephalopathy has been described in patients receiving diethylcarbamazine, especially when they are heavily infected.²³⁰ Ivermectin elicits fewer inflammatory symptoms during treatment and may be less toxic in general, but encephalopathy still can occur in patients with heavy *Loa* infections.²³² Moreover, because of the risk for encephalopathy, patients with loasis should be treated in consultation with an expert in this infection. Approaches to treatment may include plasmapheresis or a single 50-mg dose of diethylcarbamazine as for lymphatic filariasis (see earlier), gradually building to the final dose of 9 mg/kg per day over 2 weeks. In the United States, the Clinical Center of the National Institutes of Health has the greatest experience with treating *Loa* infections.

Onchocerca volvulus (and “Nodding Syndrome”)

Onchocerca volvulus infection is acquired through the bite of a *Simulium* fly, which tends to breed along rivers and streams (hence the name of the disease “river blindness”).

Epidemiology

Disease is limited to sub-Saharan Africa, where approximately 99% of the world's 17 million cases occur (approximately one-half of the cases occur in Nigeria and Congo),²¹⁷ and focal pockets near the border between Venezuela and Brazil. In view of human dependence on water and the establishment of settlements along rivers, the frequency of infection tends to be high in areas where *Simulium* prevails. The

development of hydroelectric power based on the construction of large dams can increase the breeding sites of *Simulium* and increase the incidence of *Onchocerca* infection. A neurologic syndrome associated with seizures and known as “nodding syndrome” has emerged in *O. volvulus*–endemic areas of South Sudan and Uganda. The etiology of nodding syndrome is under investigation.

Pathophysiology

Larvae deposited by a *Simulium* bite remain in the subcutaneous tissue and develop into adult worms there. Adult worms tend to become coiled, and worms of both sexes become enveloped by fibrous tissue and form nodules within which they reproduce. The larvae produced by fertilized females invade the skin, where they remain until they are picked up by a *Simulium* bite, or they die about 30 months later. In addition to the skin, microfilariae penetrate the eye and affect every layer from the conjunctiva to the optic nerve. In African onchocerciasis, chorioretinitis and optic atrophy occur commonly.

The probability of the development of eye disease is related to the location of the adult worms. When the nodules are situated around the head, eye lesions are common; when they are in the lower parts of the body, eye lesions occur less frequently. In Africa, the nodules tend to be distributed primarily in the lower parts of the body, but because of the high prevalence of the infection, onchocercal blindness is common. Hypotheses surrounding nodding syndrome are discussed in the next section.

Clinical Manifestations

The appearance of the skin nodules and the presence of live microfilariae within the eye (readily seen with a slit-lamp ophthalmoscopic examination) are the manifestations of early and intermediate disease. Later, eye involvement includes keratitis, iridocyclitis, chorioretinitis, and, eventually, blindness. Microfilariae in the skin cause an inflammatory reaction that includes acute papular onchodermatitis and chronic changes such as edema, lichenification, atrophy, and depigmentation.²²⁸ Because long-standing infection with *O. volvulus* is required to see these ocular and skin changes, these changes are often found in adults rather than in children.

However, an unusual neurologic syndrome related to onchocerciasis in children, known as nodding syndrome, has been noted in South Sudan, northern Uganda, and Tanzania.³² Nodding syndrome is a seizure-type disorder associated with unresponsiveness and paroxysms of 5 to 20 head nods/min, sometimes progressing to generalized tonic-clonic seizures, but also linked to long-term mental and developmental disabilities.³² It most commonly appears among school-aged children and adolescents.³² There is an epidemiologic association between nodding syndrome and onchocerciasis, but so far no direct causal relationship has been determined. Some investigators have hypothesized that nodding syndrome is related to host immunologic responses to *O. volvulus*,³² whereas others have suggested that blackflies may simultaneously transmit a virus that causes this condition.²³⁴

Diagnosis and Differential Diagnosis

Because skin invasion is associated with itching, the pruritus of onchocercal infection must be differentiated from that caused by contact dermatitis, prickly heat, insect bites, and scabies. Onchocerciasis is identified by examination of a skin snip. Examination of sectioned and stained tissue or a stained impression smear reveals microfilariae. Nodding syndrome should be distinguished from other forms of epilepsy on the basis of clinical criteria and analysis of cerebrospinal fluid and radiographic imaging. One of the challenges of nodding syndrome is that it mostly occurs in extremely resource-poor areas of East Africa that often do not have access to diagnostic modalities.

Treatment

Surgical removal of all visible nodules may radically extirpate the source of new microfilariae that invade the eye. The routine use of nodulectomy is still controversial, however. Chemotherapy with ivermectin (single oral dose of 150 µg/kg administered every 6 to 12 months) until asymptomatic is the treatment of choice. Ivermectin reduces the number of microfilariae in the skin within days, and subsequently the number

of microfilariae in the eye, and prevents the onset of blindness.²³³ Ivermectin also can be used in mass treatment to diminish transmission by the vector and control the incidence of this infection.^{217,218,233,236} Diethylcarbamazine is contraindicated for patients with onchocerciasis because it can lead to severe allergic symptoms, a condition sometimes known as the Mazzotti reaction.

The optimal treatment for nodding syndrome is under investigation, but it is believed that patients benefit from anticonvulsants, together with nutritional and emotional support.³¹

Prevention

Today the mainstay of river blindness control is MDA with ivermectin, which has led to the elimination of onchocerciasis in Mali and Senegal and has led to the near elimination of the disease in the six remaining Latin American countries.²¹⁷ Through The Onchocerciasis Vaccine Initiative for Africa (TOVA), a first-generation vaccine to prevent river blindness is also under development.²³⁵

Mansonella Perstans and *Mansonella Ozzardi*

Neither *Mansonella perstans* nor *Mansonella ozzardi* is known to cause significant human pathology, but the microfilariae present in blood must be distinguished morphologically from the microfilariae of the other more pathogenic filariae. *M. ozzardi* is found throughout the Caribbean (especially Haiti) and Central America. It has been suggested as a cause of chronic arthritis in these regions. *M. perstans* also is found in Africa, where it has been identified as a cause of painless nodules in the conjunctiva and secondary eyelid swelling. For that reason, it sometimes is called the Kampala or Ugandan eye worm.²³⁷ Albendazole or mebendazole is the treatment of choice for *M. perstans* infection.

Dirofilaria immitis

Dirofilaria immitis is a filarial worm commonly found in dogs, in which it occupies the right ventricle of the heart. The microfilariae produced circulate in blood and are transmitted to new animals through the bite of culicine mosquitoes. Fewer than 100 cases of human infection have been reported, none of them in children. Most human hosts infected with *Dirofilaria* were asymptomatic, but individuals who had symptoms complained of chest pain, wheezing, and cough. All infected individuals had coin lesions detected on pulmonary radiographs.^{238,239} Human infection is transmitted through a mosquito bite. As with visceral larva migrans and the zoonotic *Brugia* infections, *D. immitis* cannot complete its life cycle in humans. No microfilariae of this worm have ever been shown in human peripheral blood.

All patients evaluated for pulmonary dirofilariasis have had mild peripheral eosinophilia, usually not exceeding 10%. Because the radiographic picture is not diagnostic, and in view of the potential seriousness of a coin lesion,²³⁸ the lesion must be examined histologically. If a worm is found, the diagnosis of dirofilariasis can be made; if it is not found, the diagnosis is still tenable. In the presence of eosinophilia and pneumonitis, however, a whole range of other diagnostic possibilities must be considered, including eosinophilic pneumonia, polyarteritis nodosa, Wegener granulomatosis, and histiocytosis X. No treatment is necessary for this infection in humans.

Dracunculus medinensis

Infection with *Dracunculus medinensis* (guinea worm) is limited largely to sub-Saharan Africa. As of 2017, fewer than 100 cases remain worldwide, all in Sahelian Africa.²⁴⁰

Because filtering of drinking water can prevent this infection effectively, authorities from the WHO and the Carter Center are optimistic that this parasite will soon be eradicated through appropriate control measures.²¹⁷

OVERVIEW OF CESTODES AND THEIR IMPORTANCE FOR CHILDREN

Cestodes are multicellular helminth parasites.²⁸⁴ Children may harbor the adult worms (tapeworms) or larval stages (e.g., cysticercosis or hydatid disease). The adult tapeworms are segmented worms that contain a scolex (attachment organ); a neck region, where the segments are formed; and segments termed *proglottids*.³²⁴ The scolex contains either sucking grooves (*Diphyllobothrium* and *Spirometra*) or round suckers (other species). In some species (e.g., *Taenia solium*), the scolex is armed with rows of hooks, which also aid in attachment. The proglottids develop in the neck region and move distally as they are displaced by newer proglottids. Eventually, chains of proglottids form and compose the body of the adult worm. The external surface of the proglottid forms an absorptive surface that functions as the parasite gut. As the proglottids are displaced from the scolex, they gradually mature, with both male and female sexual organs developing in each proglottid. The terminal proglottids contain the uterus, which is full of ova. The ova of *Spirometra* and *Diphyllobothrium* are shed into water, where they infect a series of aquatic intermediate hosts. The ova of other species infect the immediate host after being ingested. Both larval and adult forms of *Hymenolepis nana* live in the human intestines, and the entire life cycle can take place in a single host. Humans are dead-end hosts for numerous zoonotic tapeworms, including *T. solium* (cysticercosis), *Echinococcus* spp. (hydatid disease), and *Spirometra* (sparganosis). The term cysticercosis (literally, “bladder tail”) refers to infection of tissues with an intermediate form of the parasite containing a cystic parasite with one (or a small number of) invaginated scolex. Human cysticercosis usually is caused by *T. solium*. However, human cysticercosis is also rarely caused by *Taenia crassiceps* or *Taenia multiceps*. *Hydatid disease* refers to infection of tissues with the intermediate form of the parasites of the genus *Echinococcus*, which form cystic lesions filled with innumerable protoscolices, each of which can turn into a tapeworm or another hydatid lesion, depending on the tissues. Infections with cestodes have been common human infections since antiquity and have been found in mummies.^{23,125} Currently, approximately 200 million people worldwide are infected by cestodes.

TAENIA SAGINATA (BEEF TAPEWORM) INFECTION

The different life cycle forms and designation of species of the beef tapeworm were identified in the 18th and 19th centuries.³¹² Although other species names have been used in the past, *Taenia saginata* is accepted now as an inclusive term for all of the species of tapeworms acquired from beef. In recent years, however, *Taenia asiatica* has been identified as a distinct species similar to *T. saginata* but acquired from pork. Differentiation of these species morphologically, however, is difficult, and identification of species is aided by DNA analysis.^{46,125}

Organism

The scolex of *T. saginata* measures 1 to 2 mm in diameter and has four muscular suckers but bears no hooks. The length of the parasite usually varies from 4 to 10 m but may reach 25 m. The size of the proglottids depends on their stage of development and their state of muscular relaxation. Gravid proglottids typically are 16 to 20 mm in length and 5 to 7 mm in width. The linear, central uterine stem has 12 to 30 main

lateral branches on each side. The eggs measure 30 to 40 μm in diameter. The six-hooked embryo is surrounded by a brown, radially striated embryophore. When the bovine host ingests the ova, embryos hatch and burrow through the intestinal mucosa, where they gain access to the circulation. After lodging in capillaries, the embryo develops into a larval cysticercus. This cystic, ovoid structure measures 7 to 10 mm \times 4 to 6 mm and contains an invaginated scolex.

Cattle are the principal intermediate hosts. Humans are the only definitive host. Ingestion of *T. saginata* eggs is of no particular danger to children because humans are not susceptible to development of the cysticercus stage.

Transmission

The life cycle of *T. saginata* requires transmission of the infection to the intermediate host and subsequently to humans, who in turn transmit the organism to other intermediate hosts. Contamination of pastures or feed lots with human feces or untreated sewage leads to bovine cysticercosis. When humans ingest raw or poorly cooked beef containing viable cysticerci, the scolex evaginates from the cysticercus and attaches to the intestinal wall. Proglottids develop from the neck region and gradually enlarge to form the adult tapeworm. Gravid proglottids, which are at the distal end of the worm, appear only 84 to 120 days after infection.²⁸⁶ Infection may persist for years. In most geographic areas, parasitism is with a single worm, but in highly endemic areas, multiple infections may be found.²⁸⁶

Ova may be found within feces. However, eggs are shed more frequently when gravid proglottids actively migrate from the anus. As these muscular proglottids crawl about, eggs are expressed from the anterior margin. The ova of *T. solium* and *T. saginata* are not distinguishable on morphologic grounds.

Epidemiology

Worldwide, 45 to 60 million people are thought to be infected with *T. saginata*. Infection is most important in tropical and subtropical cattle-raising areas of Africa, the Middle East, Europe, Asia, and South America.^{46,153} The prevalence of human taeniasis caused by *T. saginata* is poorly understood. In general, the prevalence of human infections is less than 1% of stool examinations in all but highly endemic areas, but because of the poor sensitivity of the assays, this figure may understate the prevalence. In recent studies, prevalence rates of more than 20% have been noted in East Africa, Bali, and Tibet.⁵⁰ Although the incidence of taeniasis in the United States is low, transmission does occur. However, less than 0.1% of fecal specimens examined in state health laboratories were positive for *Taenia* eggs.¹³⁹ With socioeconomic changes, improvements in the cattle industry, and decreasing instances of ingestion of undercooked beef, the prevalence of intestinal taeniasis likely will continue to drop in much of the world.

Pathology and Pathogenesis

Little is known of the pathology or pathogenesis of intestinal taeniasis. Speculation about local mucosal trauma, irritation, production of toxic substances, or induction of clinically significant hypersensitivity has scant documentation. Rare, ectopic localization of worms or proglottids may stimulate local inflammatory reactions. Some have speculated that adult worms compete with the infected host for nutrients causing malnutrition, but no good evidence exists to support this possibility.

Clinical Manifestations

A variety of symptoms have been attributed to *T. saginata*, but the parasite infection likely is often merely coincidental to the concurrently observed symptoms in the child.^{46,324} The most common complaint is the discomfort caused by the migration of gravid proglottids from the anus. Some studies of *T. saginata* infection revealed abdominal pain, nausea, weakness, and loss of weight as the most common symptoms recorded.^{46,311} Alterations in appetite and bowel habits were reported inconsistently. Intestinal obstruction and symptoms related to ectopic localization of proglottids are extremely rare. Although taeniasis usually is not associated with significant eosinophilia, some patients occasionally have significant eosinophilia between the sixth and ninth weeks after the initial infection occurs. One study reported that by the time the patients first began passing proglottids, the eosinophil counts had returned to normal or nearly normal.¹⁰⁷ Another series of observations showed a syndrome of marked eosinophilia and severe colicky abdominal pain that occurred approximately 1 month before the patients passed *Taenia* proglottids.¹¹ A single experimental infection produced symptoms of nausea, headache, and disturbed sleep at approximately the time that gravid proglottids appeared in the stool, 84 days after infection. A 10.5% increase in the number of eosinophils and a 13% increase in the number of lymphocytes were noted.²⁸⁶

Diagnosis

The scolex of *T. saginata* lacks hooks and is differentiated easily from the scolex of *T. solium*, which bears a circle of hooks. However, the scolex usually is not recovered, even after successful treatment. Studies suggest that use of polyethylene glycol salts as a purgative may improve recovery of proglottids.¹³⁷ Eggs may be seen on routine fecal wet mounts, but the likelihood of their being detected is enhanced by concentration methods. Even then, ova are shed only intermittently, and the yield of a single stool examination is low. Cellulose tape swabs applied to the anal and perianal skin, as used for the diagnosis of *Enterobius* infection, have been found to be even more efficient than fecal concentration.²⁹²

The eggs of *T. saginata*, *T. asiatica*, and *T. solium* cannot be differentiated morphologically. Thus examination of gravid proglottids is the usual method for determining species. The patient is instructed to collect proglottids in a vial of saline and to deliver the specimen to the laboratory as soon as possible. Fixatives such as alcohol and formalin tend to render the proglottids rigid and opaque. The proglottid should be compressed between two microscope slides. If the uterus contains enough ova, counting the main branches of the uterine stem is relatively easy. The uterus is more readily identified by injecting a small amount of India ink into the midportion. A count of 13 or fewer branches on one side of the stem is considered diagnostic for *T. solium*. If the count is 14 or more, the species is designated *T. saginata*. Because of morphologic variations, this method has been criticized, particularly when the decision is based on gravid proglottids with counts in the range of 12 to 15. Analysis of many specimens of *Taenia*, as identified by their scolex, showed that mature proglottids with fully developed sex organs could be differentiated by several characteristics. The most prominent features are a vaginal sphincter seen only in *T. saginata* and a third ovarian lobe that is present only in *T. solium*. To define these and other features, the proglottids require painstaking staining and clearing as well as examination by a skilled parasitologist.

Antigen detection tests are becoming increasingly useful for the identification of *T. saginata*. Tests for *T. solium* currently are more specific than tests for *T. saginata*.³ Polymerase chain reaction (PCR) testing has been useful in diagnosis of *T. saginata* in field situations.⁴⁶ On occasion, the diagnosis of tapeworm is established when larger portions of a worm appear as a ribbon-like defect in the barium column during contrast studies of the gastrointestinal tract. In plain films of the abdomen, a tapeworm may be seen as a linear density in a gas-filled loop of bowel.

Treatment

Praziquantel, a pyrazinoisoquinoline derivative, is the primary medication used to treat *T. saginata*. It is given as a single oral dose of 5 to 10 mg/kg.

An alternative to praziquantel for treatment of intestinal taeniasis is niclosamide (marketed as Yomesan in parts of Europe but not consistently available in the United States), which is given as a single oral dose of 50 mg/kg (up to 2 g for large children or for adults). Nitazoxanide, a thiazolide agent approved for use in children with other parasitic infections, has been effective in treating taeniasis that has been incompletely responsive to both praziquantel and niclosamide.¹⁵³

Because infection with *T. saginata* is not contagious, no routine follow-up is needed after treatment. If, however, proglottids are noted through the anus or in the stool more than a week after treatment is completed, subsequent therapy may be considered, perhaps with an alternative agent.

Prognosis

Symptoms, when present, may be annoying but do not usually alter health significantly. Treatment is highly effective, and the prognosis is excellent.

Prevention

T. saginata infection can be prevented by avoiding the ingestion of raw or undercooked beef. In addition, visual meat inspection is effective in detecting all but light infections. Cooking beef to a temperature of 56°C (133°F) kills cysticerci. Education of workers in the cattle-raising industry, coupled with detection and prompt treatment of human infection, may reduce the incidence of transmission. Vaccines to prevent bovine *T. saginata* cysticercosis are feasible, but development has been slowed by limited commercial interest.¹⁶⁰

TAENIA ASIATICA (ASIAN PORK TAPEWORM)

T. asiatica was identified in East and Southeast Asia, where humans become infected by eating small cysts contained in raw porcine liver. The ova and proglottids are morphologically similar to those of *T. saginata*, such that it was not recognized as a separate species until 1993.^{46,133}

Organism

Although adult tapeworm proglottids of *T. asiatica* are morphologically similar to those of *T. saginata*, the scolex contains a rostellum (like *T. solium*) but no hooks (like *T. saginata*). Proglottids usually contain 16 to 21 uterine branches, similar to *T. saginata*. The larval cysticercus stage is also similar to that of *T. saginata*, but the cysticerci generally are smaller. The cysticerci also are located primarily in the liver, not generally in muscle. *T. asiatica* cysticerci are found mainly in pigs but have been identified in cattle, goats, monkeys, and wild boar.¹³³

Transmission

Pigs (and also cattle, wild boar, and goats) become infected by ingesting *T. asiatica* eggs, which hatch, releasing the larvae, which in turn invade and develop into the cysticercal stage primarily in the liver. Animals, including humans, become infected when they ingest cysticerci (usually in raw porcine liver) and then develop the intestinal adult forms of infection. An experimental human infection demonstrated that a period of 76 days transpired between ingestion of the cysticercus and the appearance of gravid proglottids.⁷⁴

Epidemiology

Asian taeniasis has been identified in Taiwan, Korea, China, Philippines, Vietnam, Thailand, Indonesia, and Malaysia.^{46,74} It may be that other parts of the Asia-Pacific region also are endemic for *T. asiatica* but that previous surveys incorrectly identified the offending organism as *T. saginata*. The prevalence of infection varies among regions, probably related to religious and cultural choices about food; 0% to 21% of people in various parts of Indonesia are infected.³⁰⁵

Pathology and Pathogenesis

Observations in humans and studies in mice suggest that the pathogenesis of infection by *T. asiatica* is similar to that of *T. saginata*.¹³⁴ No human cysticercal form has been identified.

Clinical Manifestations, Diagnosis, Treatment, and Prognosis

The clinical manifestations, diagnosis, treatment, and prognosis of *T. asiatica* have not been described completely, but they appear to be similar or identical to those of *T. saginata*.

Prevention

Human *T. asiatica* infection can be prevented by avoiding ingestion of undercooked liver and other viscera (especially porcine).

TAENIA SOLIUM

Cysticercosis was first described in ancient Greece, where cysticerci were noted in infected pork.⁵⁷ The life cycle was clarified by the 19th century. The main clinical manifestation results from infection of the central nervous system (CNS) and is termed neurocysticercosis. Large case series describing most of the clinical manifestations were published in the early 20th century.⁶⁴ Neurocysticercosis, however, was diagnosed only rarely until the late 1970s. Subsequent advances in neuroimaging led to a dramatic increase in recognition.²²⁸ Neurocysticercosis is now recognized as among the more common causes of neurologic disease worldwide.^{24,45,83,188,193}

Organism

T. solium, referred to as the pork tapeworm, takes two distinct forms in the human host: taeniasis (tapeworm infection of the gut lumen) and cysticercosis (infection of tissues with the larval cysticercus form).⁸³ Neurocysticercosis refers to cysticercosis involving the CNS (including the subarachnoid space, spinal cord, and eyes). Humans develop the adult tapeworm after ingesting undercooked pork containing the cysticercus. The scolex evaginates in the intestines, attaches, and develops chains of proglottids. The tapeworms can be several meters long. Eggs and gravid proglottids are shed intermittently into stool. The off-white proglottids appear as flattened segments 1 mm thick and up to 2 cm in length and 1 cm in width. Pigs are infected after ingesting eggs or proglottids from human fecal material. Once ingested, the larval oncospheres emerge from the eggs, penetrate the wall of the gut, enter the bloodstream, and migrate to the tissues, where they develop into cysticerci during a period of a few weeks.

Transmission

Field studies of both taeniasis and cysticercosis are associated with tight clustering.^{89,90,156,194,200,250} Taeniasis is acquired by ingestion of undercooked pork and is closely tied to pig-raising areas in endemic countries. Most carriers are from families that raise pigs and butcher them informally in the household. Cysticercosis is acquired from the human tapeworm carriers, who not only shed eggs into the environment but also harbor eggs on their hands and fingernails. These eggs can then autoinfect the tapeworm carrier or infect other people. Thus most transmission occurs among close contacts of tapeworm carriers. Human cysticercosis is not always acquired directly from pork, as illustrated by outbreaks noted among vegetarians in India and orthodox Jews in the United States.^{252,264} In both cases, transmission has been associated with domestic servants who were tapeworm carriers, a factor also seen in urban areas lacking infected pigs.¹²⁷

Epidemiology

The global prevalence of human cysticercosis is not clearly defined. Between 50 and 100 million people are thought to be infected with cysticercosis, but far fewer with intestinal taeniasis.^{24,45,193}

In the 2015 Global Burden of Disease study,⁶³ cysticercosis was reported to affect 1,931,000 (95% uncertainty interval: 1,597,000–2,312,000) people worldwide, which resulted in 286,700 (95% uncertainty interval: 194,200–392,800) years lived with disability.

Epidemiologic studies to determine the burden of neurocysticercosis have demonstrated associations between lifetime and active epilepsy with serologic and imaging findings of neurocysticercosis.^{59,180,182,193,195,220} For instance, in Latin America more than 30% of people with epilepsy have findings compatible with neurocysticercosis.²²

Nearly all areas where pigs are raised that have access to human fecal material are endemic for cysticercosis.⁴⁵ In endemic areas, pigs

often are reared on small farms, where they are allowed to forage for food rather than being fed. Improved sanitation, meat inspection, and animal husbandry led to the eradication of cysticercosis from western Europe, which previously was highly endemic. However, similar approaches have not proved sustainable in poorer countries. Currently, porcine cysticercosis remains highly endemic in Latin America, sub-Saharan Africa, and South and Southeast Asia, as well as parts of Korea, China, Indonesia, and Papua New Guinea.^{133,194}

In the United States, porcine cysticercosis is a very rare occurrence. In contrast, human neurocysticercosis is widespread among immigrants from endemic countries.^{61,197,201,258,259,274,297} Limited transmission occurs in the United States, mainly linked to tapeworm carriers infected in endemic areas.^{53,199,259,276} Although infrequently reported, locally acquired infection has also been documented in the United States.²⁷⁵

In the United States, health care expenditure associated with neurocysticercosis is mainly due to hospitalization costs, which totaled approximately \$1 billion for the period 2003 to 2012.^{49,197,198}

Pathology and Pathogenesis

Cysticerci can develop in a wide range of tissues. In most tissues the cysticerci cause few symptoms, and their survival appears to be limited. For example, many of those infected have cigar-shaped calcifications noted on radiographs of skeletal muscle, despite the absence of musculoskeletal symptoms. By contrast, infection of the CNS often lasts for years and can cause severe symptoms.

Cysticerci mature to their full size (typically 10–20 mm in diameter) within a few weeks after infection occurs, but as illustrated in studies of British subjects returning from India and Hispanic immigrants to the United States, symptoms do not develop for several years.^{61,64} This delay may reflect the parasites' complex array of molecules used to modulate the host inflammatory response.⁸³ When the parasites lose the ability to evade immune attack, the cysticerci are attacked by a granulomatous response with a mixed cell population, including lymphocytes and mononuclear cells, with variable numbers of eosinophils and neutrophils.^{102,119,225,226,230,260} This granulomatous host response to the parasite, when it is present in the brain parenchyma, is thought to be the cause of seizures, the characteristic clinical feature of parenchymal neurocysticercosis.²⁷⁹ During the course of several months, the inflamed parasite is invaded by inflammatory cells, the cyst cavity collapses, and the parasite material is replaced by the host granulomatous response.¹¹⁹ The lesion eventually either resolves or is replaced by a small calcified granuloma. The calcified lesions contain a mixture of fibrosis and residual parasitic debris. An intermittent inflammatory response to persistent parasitic antigen may manifest as perilesional edema in calcified lesions,⁸² and it may be the cause of recurrent seizures in patients with cerebral calcifications.^{186,189} Rarely, massive infection is accompanied by a diffuse cerebral edema.^{223,290}

Extraparenchymal neurocysticercosis is associated with a poorer prognosis, largely because of production of hydrocephalus.⁹⁹ Parasites can cause obstructive hydrocephalus by lodging in the outflow tracks of the cerebral ventricles. Cysticerci in the basilar cisterns often are associated with chronic arachnoiditis. This basilar inflammation may lead to chronic meningitis (with headache and nuchal rigidity but usually without fever), vasculitis and strokes, or communicating hydrocephalus. Less frequently, cysticerci in fissures enlarge to 5 cm or larger (termed giant cysticerci). The parasites, along with accompanying cerebral edema, may cause a mass effect. In patients with multiple cysticerci, several forms of the disease can be present at the same time.

Clinical Manifestations

Taeniasis

Taeniasis typically causes few symptoms. Cases have been associated with vague abdominal complaints and occasionally pruritus. The most specific symptom is the passage of proglottids in the stool. The proglottids appear flattened (typically 0.3–0.5 cm wide × 1 to 2 cm long and 1 mm thick). Each segment has 13 or fewer uterine branches. Unlike *T. saginata*, the proglottids usually are single and seldom are noted to be motile.

Cysticercosis

The clinical manifestations of cysticercosis are variable,^{99,326} depending on the location of the parasites, their number, and the host inflammatory

response. Experts now group neurocysticercosis into a range of syndromes that differ in pathogenesis, clinical manifestations, prognosis, and management.^{83,88,99,188}

Single enhancing lesions. The most common presentation in children with neurocysticercosis is with seizures and a single enhancing lesion on neuroimaging studies.^{95,238,240,244,260,265,282,302} Most cases are manifested with seizures, which can be isolated or recurrent. The seizures typically are focal with secondary generalization, although they may be focal or generalized.^{263,268,269,302} Some children experience only severe headaches,²¹⁶ which can resemble either tension headaches or migraines. Imaging studies of children reveal either a focal area of enhancement or a ring-enhancing lesion, often with surrounding edema. Lesions typically are found within the cortex.

Multiple cystic (viable) lesions. Similar to children with single enhancing lesions, patients with multiple parenchymal cysticerci also have seizures. The seizures more often are generalized or focal with secondary generalization but also may be focal.^{30,101,268} Neuroimaging studies demonstrate edema, contrast enhancement, or both for one or more parasites, and symptoms are thought to result from the host inflammatory response. Noninflamed cysts cause few symptoms, even when they are numerous,⁸⁴ but they pose a risk for development of recurrent symptoms when they degenerate.

Other symptoms include headaches. Infection has been associated with learning disabilities,^{42,157,231,240,304} but these findings may be the result of either poorly controlled seizures or hydrocephalus.²⁸⁵ An association of cysticercosis with depression and occasionally psychotic episodes also may exist.⁷⁹

Cysticercal encephalitis. Some children have diffuse cerebral edema from large numbers of inflamed cysticerci, termed cysticercal encephalitis. The clinical presentation includes signs or symptoms of raised intracranial pressure, seizures, and altered mental status.^{223,290} Cysticercal encephalitis is thought to result from a brisk inflammatory response to a massive infection and is seen more frequently in children and women than in adult men. This pathogenesis is the direct result of the host inflammatory response, and the key to management is to address inflammation and cerebral edema. Antiparasitic drugs are contraindicated because they can worsen the cerebral edema.

Parenchymal calcifications. Resolution of neurocysticercosis can be associated with the formation of calcified granulomas within the brain parenchyma.¹⁸⁸ The calcifications appear as well-defined calcified nodules measuring 2 to 10 mm. The calcified lesions contain fibrotic reactions, parasite debris, and calcium deposits, with variable degrees of inflammation.¹⁸⁶ Patients frequently present with seizures.^{187-190,266} The most common imaging finding from neurocysticercosis in population-based studies in endemic villages is with focal calcifications.^{59,78,180,220} Few patients will have focal abnormalities on electroencephalographic studies.³⁴ Among patients with seizures, calcified lesions are a risk factor for having recurrent seizures.^{27,105,190,220} Patients with seizures and calcifications should be treated with antiepileptic therapy indefinitely. About half of patients with calcified neurocysticercosis and seizures have associated enhancement and edema on magnetic resonance imaging (MRI) studies.^{10,190} Rather than revealing viable parasites, the enhancement may result from breakdown of the calcified granulomas, with release of antigen resulting in restimulation of the host inflammation.^{118,190}

Ventricular neurocysticercosis. Approximately 10% to 20% of adult patients with cysticercosis have cysticerci in the ventricles,^{83,191,224,245,259} but the numbers often are lower in children.²⁴⁴ Cysticerci are found in any of the ventricles, but symptoms are particularly associated with obstruction of the outflow of the third or fourth ventricle at the cerebral aqueduct or foramina of Luschka and Magendie. In contrast to parenchymal disease that largely results from the host inflammatory response, symptoms of ventricular disease result from mechanical obstruction typically caused by viable parasites.¹⁴² Within the thin-walled viable cysticerci, the cyst fluid often is isodense with cerebrospinal fluid (CSF), rendering them difficult to detect. Computed tomography (CT) scanning may show only obstructive hydrocephalus or distortion of the shapes of the involved ventricle. Even on MRI, the findings may be subtle and can be missed by inexperienced observers unless the patients have concomitant parenchymal cysticerci.^{122,317,319} Newer three-dimensional

MRI sequences (e.g., FIESTA, 3D CISS) may improve visualization of cysts in the ventricles or subarachnoid space.^{32,115}

Symptoms from ventricular neurocysticercosis usually result from raised intracranial pressure and include headache, nausea or vomiting, altered mental status, papilledema with visual changes, or dizziness. The onset is extremely variable from chronic intermittent headache to sudden loss of consciousness.²⁹⁶

Subarachnoid cysticercosis. Subarachnoid cysticercosis can also be quite variable. Small cysticerci in the gyri have a clinical presentation and prognosis similar to those of parenchymal cysts, although they are associated more often with CSF pleocytosis, may be slightly larger, and respond less well to antiparasitic drugs.^{83,245} Cysticerci in the basilar cisterns can cause arachnoiditis, leading to CSF outflow obstruction, communicating hydrocephalus, vasculitis, and strokes.^{83,277} In the era before antiparasitic drugs were available, this form carried a high case-fatality rate.²⁷⁷ By contrast, more recent case series have been characterized by low mortality rates.^{45,54,191,224,259}

Most patients with cysticerci in the basilar cisterns are infected with large numbers of parasites, and they frequently have coexisting ventricular or parenchymal as well as subarachnoid disease. Symptomatic cysticerci in the basilar cisterns typically are accompanied by chronic arachnoiditis. This arachnoiditis may present as meningitis with headache, stiff neck, and CSF pleocytosis, but it usually is not accompanied by fever. Patients often develop communicating hydrocephalus (headaches, nausea, vomiting, and dizziness). Basilar cysticercosis frequently involves the basilar vasculature either by direct invasion or by inducing vasculitis. Thus patients may present with cerebrovascular accidents, which may involve either small vessels with lacunar infarctions from vasculitis or large vessel strokes (associated with invasion of the vessel wall by the parasite).^{13,56,86} Some patients present with intracerebral hemorrhages.³⁰³

Giant cysticerci. Cysticerci can develop in the fissures (especially the sylvian fissure) and may enlarge to more than 5 cm in diameter; these are called giant cysticerci.²¹¹ In some cases, the cysticerci can lose the scolex and may grow as clusters of cyst walls (termed racemose cysticercosis). Giant cysticerci not only are associated with symptoms of parenchymal inflammation but also can cause mass effects such as midline shift. Frequently, giant cysticerci are accompanied by cysticerci in the parenchyma or basilar cisterns. Giant cysticerci are readily visualized by CT or MRI, but the accompanying basilar cysticerci may not be seen as easily.

Other forms of cysticercosis. Neurocysticercosis rarely is limited to the spine, but spinal disease is common with subarachnoid disease.²⁹ Most patients present with radicular pain and, less frequently, myelitis. In most cases, cysticerci are in the spinal fluid, but they also can be intramedullary cysticerci.¹⁵⁵ The intramedullary form typically presents with myelitis. Orbital involvement includes subconjunctival cysticerci and involvement of the extraocular muscles.^{39,215,257} Intraocular disease may be subretinal, intravitreal, or within the anterior chamber. Skeletal muscle involvement typically is asymptomatic, but it may result in pseudohypertrophy or weakness with massive infection. Subcutaneous lesions typically present as one or more painless mobile cystic lesions. Subcutaneous disease is more commonly noted in Asia and Africa than in the Western Hemisphere.

Diagnosis

Taeniasis

Taeniasis has been diagnosed traditionally by examination of the stool for proglottids, ova, or both. The ova and proglottids are shed only intermittently, and collection of stool specimens from children can prove difficult. Furthermore, the sensitivity of stool microscopy for ova is only 26%,⁵ and the ova of *T. solium* and *T. saginata* are indistinguishable, which limits the specificity of the assay. Identification of species requires collection of the proglottids, which can be facilitated by treating the patient with polyethylene glycol.¹³⁷ The proglottids of the two species can be distinguished by counting the number of uterine branches. *Taenia saginata* proglottids usually have 15 or more uterine branches, compared with less than 13 branches in those of *T. solium*.

More sensitive and specific techniques are available only as research tools. Antigen-detection assays have a specificity of 99.2% and a sensitivity

of 70% to 92%,^{4,5,233} but most cannot distinguish *Taenia* spp. Enzyme-linked immunotransfer blot to identify serum antibodies to *T. solium* tapeworm-stage antigens may be more sensitive than are stool-based tests and seem to be specific for the *T. solium* tapeworm stage.^{120,158,308} However, the antibody may persist after treatment. PCR techniques can be used to improve sensitivity and specificity compared with stool microscopy and to differentiate *Taenia* species.^{114,171}

Neurocysticercosis

Establishing the diagnosis of neurocysticercosis is more difficult than with many other parasitic infections. The major clinical presentations are nonspecific, and the location of the parasites within the CNS usually precludes their being observed directly. Serologic tests using crude antigens (including a number of commercially available enzyme-linked immunosorbent assays [ELISAs]) are plagued by poor sensitivity and specificity. However, computerized imaging methods (e.g., CT and MRI) have led to a dramatic increase in the ability to recognize cases and are now the mainstay of diagnosis (Figs. 227.1 to 227.3), although even these techniques cannot always distinguish neurocysticercosis from other neurologic processes.

An expert group proposed diagnostic criteria based on neuroimaging studies, serologic tests, clinical history, and exposure.^{58,325} The presence of either a single absolute criterion or two major criteria along with two minor or epidemiologic criteria is considered diagnostic. One major criterion plus two other criteria or three minor criteria along with exposure define a probable diagnosis.

Direct visualization of the parasite on ophthalmoscopic examination or histology is considered diagnostic of neurocysticercosis.⁵⁸ However, biopsy or autopsy material demonstrating *T. solium* parasites rarely is available, and parasites seldom are visualized in the eye. The neuroimaging pattern of a cystic lesion with a mural nodule measuring 1 to 3 mm (consistent with a scolex) is thought to be pathognomonic for cysticercosis.^{317,318} However, rare cases have been reported in which similar findings have been noted in other diseases, and even in neurocysticercosis, the scolex cannot be visualized in most cases.

The main major diagnostic criterion for neurocysticercosis is one or more lesions on neuroimaging studies highly suggestive of neurocysticercosis.^{58,55} Viable cysticerci appear on CT or MRI scans as rounded fluid collections typically 1 to 2 cm in diameter. The cyst fluid is isodense with CSF (hypodense in contrast to brain tissue on CT or T1 imaging). The scolex sometimes is visible as a small nodule found attached to

the cyst wall. The wall of the cysticercus initially is isodense with the parenchyma and not easily visualized. On T2-weighted and fluid-attenuated inversion recovery images, the fluid is seen as hyperintense. Inflamed cysticerci are characterized by perilesional edema and contrast enhancement.²⁷⁹ Subsequently, the cyst fluid increases in density and becomes infiltrated by host inflammatory cells. The cyst cavity eventually collapses, forming a solid area of focal enhancement. At that point, the granulomatous inflammation either resolves or leads to the formation of a calcified nodule typically measuring 2 to 6 mm in diameter. CT is better than MRI to detect calcifications; however, MRI is superior to detect associated perilesional edema. In addition, MRI, especially 3D sequences, is the imaging procedure of choice for intraventricular cysts and cysts located in the basilar cisterns, posterior fossa, and brain convexity.^{32,85}

FIG. 227.3 Neurocysticercosis with parenchymal involvement. (Courtesy C. Mark Mehringer, MD, Harbor-UCLA Medical Center.)

Although enhancing lesions are typical of neurocysticercosis, similar lesions can be noted with tuberculomas, brain abscesses, and tumors. Rajshekhar and Chandy²¹⁸ noted that cysticercal lesions typically have a diameter smaller than 20 mm and rarely cause midline shift. A single, round, enhancing lesion less than 20 mm in diameter without midline shift on imaging studies in patients lacking signs or symptoms of systemic disease, focal neurologic deficits, or increased intracranial pressure was highly suggestive of neurocysticercosis in a prospective study of 401 patients in southern India.²¹⁸ However, the results are less specific in areas with a lower prevalence of cysticercosis. Spontaneous resolution or resolution achieved with antiparasitic drugs is another major criterion.

Serodiagnosis has proved problematic for cysticercosis. ELISAs employing unfractionated antigens, such as cyst fluid, have poor sensitivity and specificity.^{212,221} The preferred serodiagnostic test is the enzyme-linked immunotransfer blot employing semipurified parasite glycoproteins.²⁹⁸ A positive reaction to any one of seven glycoprotein bands is considered positive. ELISAs using recombinant versions of these antigens are being developed.^{87,120,121,254} Studies have confirmed a specificity of nearly 100% in suspected cases, but the sensitivity is limited in subjects with either a single lesion or only calcified lesions.^{108,212,253,310} For this assay, tests of serum are more sensitive than tests of CSF.³¹⁰ Assays to detect parasite antigens may prove to be important diagnostic studies in the near future.^{75,94,97,100,205} Minor criteria include (1) lesions on neuroimaging studies consistent with neurocysticercosis but less suggestive (e.g., isolated basilar meningitis, hydrocephalus without demonstration of cystic lesions, or filling defects in the spinal subarachnoid space without discrete cysticerci), (2) symptoms suggestive of seizures or hydrocephalus, and (3) cysticercosis outside the nervous system (e.g., cigar-shaped muscle calcifications or subcutaneous nodules).⁵⁸ Epidemiologic criteria include residence or prolonged visits to endemic areas and contact with a tapeworm carrier. Since the guidelines were published several publications have reported detection of parasite antigens in CSF, serum, and urine.^{52,184,232,306} Currently no commercial or well-standardized assays are available. Antigen is more frequently detected with viable cysticerci and with a larger parasite burden. They appear to be particularly useful for determining length of therapy in complicated subarachnoid cases. PCR assays have been reported on CSF, but these are also not well standardized.¹⁷⁵

Numerous other tests may prove useful in excluding other illnesses but are not diagnostic of neurocysticercosis. These tests include blood counts, lumbar puncture for testing of CSF, and stool studies. Lumbar CSF frequently has elevated protein levels and may show hypoglycorrhachia. Cell counts are variable and may demonstrate a predominance of lymphocytes, neutrophils, or eosinophils.

Treatment

For patients with seizures caused by neurocysticercosis, initial management should focus on control of the seizures, which usually can be accomplished with a single antiepileptic drug.³²⁶ Most published studies describe use of phenytoin or carbamazepine. Newer agents (e.g., valproate, lamotrigine, levetiracetam, topiramate, oxcarbazepine, or clobazam) may be more effective, but they are not affordable in endemic areas.¹⁴¹ Breakthrough seizures usually occur with subtherapeutic antiepileptic drug levels, often from poor adherence to medication therapies.⁸¹ Seizure therapy can be tapered off for many patients after they have a seizure-free period if radiographic resolution of the lesion is seen. However, a substantial risk exists for recurrence of seizures if residual inflamed or calcified lesions are present.^{30,101,190,219,302} Antiepileptic drugs should be continued indefinitely if calcifications develop.

Patients with obstructive hydrocephalus usually require surgery.^{83,88,188,191,224} For patients with mild or intermittent symptoms (e.g., a cysticercus in the lateral ventricles not associated with midline shift), elective endoscopic removal of the cysticercus is the treatment of choice.^{217,224} Cases with altered mental status or impending herniation should undergo emergency CSF diversion by a ventriculostomy or placement of a ventriculoperitoneal shunt. A high rate of shunt failure exists if shunting is not followed by administration of antiparasitic therapy or corticosteroids.^{83,142,224,277} Patients with communicating hydrocephalus often require placement of a ventriculoperitoneal shunt.¹⁴²

In some patients, cysticerci and associated edema may lead to mass effects. If the symptoms are life-threatening or if the cysticercus is easily approachable (e.g., in the sylvian fissure), surgical decompression of the cysticercus is the preferred approach.

A consensus is emerging among experts about the proper role of antiparasitic drugs and corticosteroids in the management of neurocysticercosis.⁸³ Experts agree that neurocysticercosis represents a spectrum of diseases that differ in optimal management.

Single Enhancing Lesions

The most common presentation of children with neurocysticercosis is seizures and a single enhancing lesion. Seizures generally can be controlled with antiepileptic medications.^{141,219,302} Controlled trials of antiparasitic drugs in patients with single enhancing lesions have demonstrated a favorable prognosis with symptomatic therapy. However, the length of time until radiologic resolution is achieved and the duration of time for risk for experiencing seizures appear to be somewhat shorter with antiparasitic drug treatment.^{204,265,267,293,321} By contrast, these treatments do not appear to affect the formation of calcified lesions or development of chronic epilepsy. The role of steroids is better defined; several studies showed clear benefit in reducing seizure activity and faster resolution of the lesion on CT when steroids were used in conjunction with antiepileptic medications.^{104,106,150,168,209} Overall, the best evidence points to a small benefit achieved from use of antiparasitic drugs (e.g., albendazole 15 mg/kg per day for 7–14 days)³²¹ accompanied by corticosteroids (e.g., prednisone 1 mg/kg per day during antiparasitic therapy). A single study that used combinations of praziquantel 75 mg/kg per day and albendazole 15 mg/kg per day suggested enhanced cysticidal activity in children with single enhancing lesions compared with albendazole alone.¹⁴⁰

Multiple Parenchymal Lesions

Patients with seizure activity with multiple cysticerci usually will have one or more lesions in the process of degeneration (e.g., edema or contrast enhancement on imaging studies). However, other cysticerci may be in the viable stage, posing a prolonged risk for having seizures. A placebo-controlled trial from Peru showed a modest reduction in the number of generalized seizures in patients treated with albendazole and corticosteroid,¹⁰¹ but no decrease occurred in the development of chronic calcifications. A second study from Ecuador demonstrated similar results.^{31,237} Overall, the current expert consensus is that patients with multiple parenchymal cysticerci usually should be treated with a course of an antiparasitic agent (albendazole 15 mg/kg per day in two daily doses for 7 to 10 days) and a simultaneous course of corticosteroids.¹⁹¹ More recent data from randomized clinical trials demonstrated that the combination of praziquantel and albendazole was more effective than albendazole alone. Combination therapy led to higher cystic resolution at 6 months in patients with multiple cysts (e.g., those with more than two parenchymal cysts).^{91,98} Even so, symptomatic therapy (e.g., antiepileptic drugs) remains a key to management. A study evaluating the effect of antiparasitic therapy in addition to corticosteroids showed that a 4-week course of dexamethasone compared with a 10-day course resulted in fewer seizures early after starting therapy. However, the beneficial effect was not significant after 3 weeks of follow-up.⁹²

Cysticercal Encephalitis (Numerous Cysticerci With Cerebral Edema)

In this context of diffuse cerebral edema (cysticercal encephalitis), antiparasitic drugs are contraindicated because of their potential to exacerbate host inflammatory responses.^{88,222,289} Most cases will resolve spontaneously with antiinflammatory medications.

Calcified Parenchymal Cysticerci

Parenchymal brain calcifications can be seen in more than 10% of residents in some neurocysticercosis endemic areas.^{188,220} These parenchymal calcifications are a significant risk factor for having continued seizure activity.^{103,219,302} If a patient with a history of seizures has a calcified lesion, that patient should be treated with antiepileptic therapy indefinitely. Recurrent seizures may be due to concomitant mesotemporal sclerosis.³⁰¹ Antiparasitic medications and antiinflammatory drugs are

not indicated. Surgical removal of the calcified focus has been used in some cases of intractable seizures.³⁰⁷ By contrast, most cases can be managed with a single antiepileptic medication. About half of cases demonstrate perilesional edema or enhancement on MRI. Some have tried antiinflammatory therapy, but steroid withdrawal can actually precipitate symptoms.¹⁷⁴

Ventricular Neurocysticercosis

Patients with obstructive hydrocephalus usually require surgery.³²⁶ As mentioned earlier, for mild or intermittent symptoms (e.g., a cysticercus in the lateral ventricles not associated with midline shift), elective endoscopic removal of the cysticercus is the treatment of choice.^{88,128,214,217,224,281} Cases with altered mental status or impending herniation should undergo emergency CSF diversion by a ventriculostomy or placement of a ventriculoperitoneal shunt. A high rate of shunt failure exists if shunting is not followed by administration of antiparasitic therapy. Cysticerci in the lateral and third ventricles usually can be removed through a rigid endoscope. A flexible endoscope is required to approach the fourth ventricle or basilar cisterns.^{129,296,322} Many surgeons, however, prefer a suboccipital craniotomy for removal of cysticerci in the fourth ventricle. Endoscopic foraminotomy and third ventriculostomy often can be used to treat residual hydrocephalus. Antiparasitic medications should not be given before the procedure is performed because they can cause the cysticerci to be friable or to adhere to the ventricular wall. The cysticerci frequently rupture during removal, but this rupture has not been associated with any adverse effects. Endoscopic third ventriculostomy has been used as an alternative to shunting procedures.^{128,151,213}

A ventriculoperitoneal shunt may be used to treat hydrocephalus. The rate of shunt failure is high in patients treated only with ventriculoperitoneal shunting. However, shunt failure appears to occur less frequently when patients receive adjunct therapy with corticosteroids and antiparasitic drugs. Although some patients have been treated with only chemotherapy and steroids, a substantial risk exists for development of acute hydrocephalus from cysticerci or accompanying inflammation causing obstruction of the foramina.

Subarachnoid Neurocysticercosis

Basilar subarachnoid cysticercosis is perhaps the most severe form of infection and carries risks for communicating hydrocephalus, vasculitis, and strokes.^{83,188} Data on how best to treat this form are limited, but most experts agree that patients should be treated with antiparasitic drugs, corticosteroids, and, in most cases, CSF diversion procedures.^{211,326} Most experts recommend treatment with albendazole, typically 15 mg/kg per day in divided doses for at least 28 days, but cure rarely is achieved with a single course of albendazole. Repeated courses, prolonged therapy, higher doses, switching to praziquantel, and combination of the two drugs have been tried in some cases.^{112,169} Improved responses have been noted with endoscopic debulking of some of the parasites,^{116,191} but this approach has not yet been studied systematically.

Inflammation seems to drive much of the pathogenesis, and the residual symptoms may reflect a chronic inflammatory response to cysticercal antigens rather than viable cysticerci. Prednisone up to 60 mg/day or dexamethasone up to 24 mg/day should be used along with the antiparasitic drugs. After 2 to 4 weeks, the dose often can be tapered. In cases that require more prolonged steroid therapy, methotrexate has been used as a steroid-sparing agent.¹⁷⁷

Giant Subarachnoid Neurocysticercosis

Some cysticerci, particularly in the sylvian fissure or basilar cisterns, may enlarge to more than 5 cm in diameter, causing mass effect either directly or by surrounding edema. If mass effect cannot be reversed quickly by corticosteroids, surgical decompression may be required. In the absence of symptomatic mass effect, however, giant cysticerci can be treated similarly to other subarachnoid cysticerci.^{191,211}

Other Forms of Neurocysticercosis

Cysticercosis of the eye, spine, or subcutaneous tissue generally is treated by surgical removal.⁸³ Anecdotes of medical therapy also exist.

Prognosis

The prognosis of neurocysticercosis is extremely variable, depending on the type of infection. Patients with single enhancing lesions generally do well and often are seizure free and discontinue therapy within 1 to 2 years. Patients with calcified lesions may require chronic antiepileptic therapy. Patients with numerous subarachnoid cysticerci often require repeated courses of therapy and even repeated surgeries. However, with optimal management of hydrocephalus, cases are rarely fatal.

Prevention

Cysticercosis was eliminated from western Europe by improved sanitation, animal husbandry, and meat inspection.^{93,113} For example, porcine cysticercosis can be prevented by not allowing pigs access to human feces.³⁰⁰ However, confined pigs must be fed, which is not affordable for peasant farmers. Human infection with adult tapeworms also can be prevented by adequate cooking or freezing of infected pork, but meat inspection has not been successful in areas where pigs are slaughtered informally.²⁸⁷ Mass chemotherapy of endemic populations for carriage of the human tapeworm or porcine cysticercosis has resulted in significant short-term decreases in prevalence,^{4,113,249} but prevalence rates rapidly return unless mass treatment is continued. A recent study demonstrated sustained elimination of cysticercosis from northern Peru by the combined use of mass chemotherapy to eliminate human tapeworm carriage, mass chemotherapy of pigs to eliminate porcine cysticercosis, and vaccination of pigs.⁹⁶

COENUROSIS (*TAENIA MULTICEPS*, OTHERS) AND CYSTICERCOSIS CAUSED BY *TAENIA CRASSICEPS*

Several species of *Taenia* have a larval stage called a *coenurus* that consists of a cystic membranous structure measuring up to 6 cm in diameter from which multiple scolices bud internally or externally.^{119,131} On the basis of this morphologic appearance, the parasite was given the species name *multiceps*. Currently the preferred genus name is *Taenia* because of the morphology of the adult worms and the inability to justify a genus designation based solely on the form of larvae. The following species generally are accepted for purposes of discussion. The adult tapeworm of *T. multiceps* is found in dogs, and the larval stages occur in herbivores. The larvae often develop in the CNS in sheep. In sheep-raising areas of Europe and Asia, the infection is still endemic in animals. *Taenia serialis* adult worms are found in dogs and other canids, but common intermediate hosts are rabbits, hares, and rodents. The coenurus develops in subcutaneous and intramuscular tissue. *T. serialis* has been reported from the United States, Canada, France, and Africa. *Taenia brauni* is the name given to the tapeworms of dogs, jackals, foxes, and genets found in tropical Africa. The larvae develop in gerbils and other rodents. Humans are a rare accidental host for the larval stages of these worms. Fewer than 100 human infections have been recorded. Most infections are from Africa, with many occurring in children. Giving a species designation based solely on the morphologic features of organisms recovered from human tissue is nearly impossible. The infection is presumed to be acquired by the ingestion of eggs excreted by the definitive hosts, usually dogs. Because of the subcutaneous and subconjunctival locations of cysts in infections in tropical Africa, some researchers have suggested that direct contact of the eggs on skin or the conjunctiva is a mode of transmission. A review of the six human infections in North America has been published.^{119,131}

The clinical manifestations of coenurosis are related to the location of the parasite. Involvement of the CNS produces a spectrum of illness that resembles that of cysticercosis (discussed earlier), including meningeal reactions. Larvae have been seen in the subconjunctival and subretinal tissue, the extraocular muscles, the anterior chamber, and the vitreous. Subcutaneous and intramuscular lesions occur most commonly in the abdomen and chest wall. A definitive diagnosis is made by demonstrating the characteristic morphologic features of the larva recovered at surgery. The multiple scolices that bud from the delicate cyst membrane have double rows of hooklets of a typical shape,

size, and number. In instances in which no scolices are found, differentiation of a coenurus from a cysticercus of *T. solium* is impossible. The diagnosis of intramuscular coenurosis has been made by examination of fine-needle aspirates.^{119,131} Radiographic studies such as CT are useful in cerebral coenurosis but do not differentiate the parasite from other cystic lesions. The metabolic changes of magnetic resonance spectroscopy in an adult with cerebral coenurosis have been reported.⁷ Treatment is surgical. Mortality rates in cerebral disease are high. Organisms in other locations, with the exception of subretinal lesions, are removed easily. A combination of praziquantel and albendazole have been used administered to a patient with a subretinal coenurus caused death of the parasite, which resulted in a severe inflammatory reaction, retinal detachment, and permanent loss of vision.¹³⁰ Severe reactions were reported in the two additional cases described in this review. Praziquantel should be used with great caution, if at all, in cases of human coenurosis. Nonetheless, postoperative praziquantel and albendazole have been used without apparent complication.^{14,73} Although the exact mode of infection in humans has not been identified, avoidance of close contact with dogs and dog excreta, which are the most likely sources of infection, is prudent.

T. crassiceps cysticerci usually are found in field mice, with the tapeworm found in foxes, other canids, and felines. There have been a few reported human cases with ocular disease or mass lesions in compromised hosts (e.g., patients with acquired immunodeficiency syndrome).^{35,40,81,110,124,167} Experimental *T. crassiceps* infection induces a helper T-cell subtype 2 (Th2) response that can also modulate immune responses to subsequent pathogenic challenges.²²⁷ Fluid from *T. crassiceps* vesicles has been used to develop ELISA tests, but these tests are not specific for *T. crassiceps* infection and are rather used for seroprevalence studies of neurocysticercosis resulting from *T. solium* infection.^{132,210} The diagnosis and management of *T. crassiceps* infection require surgery, but anthelmintic treatment might play a helpful role.¹¹⁰

DIPHYLLOBOOTHRIUM SPECIES (FISH TAPEWORM)

Diphyllobothriasis can occur in children who ingest raw, pickled, or undercooked fresh-water fish.³²⁴ The prevalence of infection increases with age in endemic areas. Nonspecific gastrointestinal complaints may occur in infected individuals, and megaloblastic anemia has been described particularly among elderly people in northern Europe and Chile.^{46,138,203,256,312}

Several species of *Diphyllobothrium* have been reported in humans. *Diphyllobothrium latum*, the most common, was described first in 1592 from specimens found in Switzerland; it is now estimated to infect approximately 9 million individuals worldwide, with most cases occurring in Europe.⁶⁸ *Diphyllobothrium pacificum* is a similar fish tapeworm found infecting humans in Japan and South America, and *Diphyllobothrium nihonkaiense* has been described in humans from the North Pacific Basin including Japan, China, and Korea.^{38,46} The *Diphyllobothrium* spp. typically have dogs, cats, foxes, bears, fish-eating birds, and marine mammals as definitive hosts, but children living in endemic areas may be infected when they eat raw or undercooked fish.

Organism

The scolex of *D. latum* possesses neither discrete suckers nor hooks but has two deep grooves called *bothria*. The worm may be as long as 15 m. The gravid proglottids have a characteristic rosette-shaped central uterus. Eggs measure 55 to 61 μ m by 37 to 56 μ m and have light-brown, operculated shells. The eggs are shed in an unembryonated state from a uterine pore into the fecal stream. The embryos develop within the eggs in fresh water. The ciliated embryos hatch and are ingested by copepods to develop further. After the fish have ingested the infected copepod, the larval stages develop into the plerocercoid stage in the muscles of fish. As the smaller fish are eaten by larger species, the larvae parasitize the muscles of the new host. Eventually, the larvae are found in fish that are sources of food for humans, such as species of pike, perch, turbot, lake trout, and whitefish. The plerocercoid larvae or spargana are white, ribbon-like worms approximately 5 cm in length.

Transmission

Children can be infected by ingesting the infectious plerocercoid forms in raw or undercooked fish muscle. Cooking and freezing kill the larvae, but smoking and pickling fish does not. The cycle of infection is perpetuated by the discharge of untreated human sewage into fresh-water lakes and streams. Diphyllobothriasis is a problem in the aquaculture industry, with some countries reporting high rates of plerocercoid forms in feral fish in lakes where salmon is farmed.^{28,239} Outbreaks of diphyllobothriasis associated with the consumption of raw imported farmed salmon have been described.^{247,248}

Some fish-eating mammals also may serve as definitive hosts for *D. latum* and maintain the cycle of infection in the absence of humans. Other *Diphyllobothrium* species (e.g., *D. pacificum*) have a life cycle involving the marine environment and use marine fish and mammals like seals and sea lions as intermediate and definitive hosts, respectively. Because *Diphyllobothrium* spp. requires intermediate hosts, direct transmission cannot occur, and no techniques of isolation or special precautions are required for infected patients.

Epidemiology

The prevalence of infection increases with age in endemic areas. However, infections have been reported in children younger than 1 year of age.⁴⁶ The disease has a worldwide distribution, but a higher prevalence is described in areas where fresh-water fish is eaten raw, lightly salted, pickled, smoked, or partially cooked. Infection occurs frequently in the Baltic countries and Russia; Scandinavia; Switzerland and the adjacent lake regions of Italy, France, and Germany; the Danube River delta; the lake areas of the northern United States and river deltas of Alaska; and Canada, South America, and China.¹¹⁷ Pediatric infection by *D. latum* has also been identified in school-aged children in India, Taiwan, Korea, Argentina, and Hawaii. Salmonid fish (i.e., salmon, trout, whitefish) transmit *D. nihonkaiense* to humans in Japan, China, and Korea.^{38,320} Infection of humans with *D. pacificum* has been reported from Peru and Chile after the ingestion of salt water fish such as bonito and lorna drum.^{138,256}

Pathology and Pathogenesis

Little is known about the direct effects of the parasite on the host. Megaloblastic anemia has been described in infected individuals in Northern Europe and Chile, but not in other regions.²⁰⁶ The following factors may be significant in the pathogenesis of "tapeworm anemia": (1) the strains of *D. latum* found in Finland, where anemia occurs, absorb seven times more vitamin B₁₂ than do strains from North America, where anemia has not been reported; (2) interference with absorption of vitamin B₁₂ occurs in nonanemic carriers as well as in those with anemia, and deficient stores of vitamin B₁₂ plus malabsorption of vitamin B₁₂ may contribute to the anemic state; (3) dietary intake of vitamin B₁₂ may be low in anemic patients, and oral vitamin B₁₂ has been shown to cause reticulocytosis in the presence of the worm; (4) worms found in anemic patients take up more of an oral dose of vitamin B₁₂ than do worms in asymptomatic carriers, and worms are attached more proximally in the small intestine in anemic patients; and (5) secretion of intrinsic factor is reduced in anemic patients. Thus host and parasite factors likely play a role in the development of megaloblastic anemia in diphyllobothriasis.

Clinical Manifestations

Most infections are asymptomatic, but patients may notice proglottids or tapeworm segments in the stool. In Finland, comparison of symptoms between nonanemic infected patients and uninfected controls revealed an increase in fatigue, weakness, craving for salt, lack of well-being, dizziness, and numbness of the extremities in the infected group.²⁴¹ Significant gastrointestinal symptoms occur infrequently. However, an experimental infection with seven larvae produced nausea, severe periumbilical pain, and marked weight loss. Episodes of intestinal obstruction associated with the vomiting of masses of tapeworms have been reported. Eosinophilia is an uncommon finding. Patients with *D. pacificum* reported abdominal pain, vomiting, diarrhea, and flatulence.¹⁶⁴ Megaloblastic anemia caused by *D. latum* infection is extremely rare

outside Finland and neighboring endemic areas. In addition, no other *Diphyllbothrium* species have been associated with anemia. Usually, it is seen in patients older than 50 years of age (and may occur in as many as 2% of adult tapeworm carriers), but it has been reported in children as young as 9 years.

Diagnosis

Identification of the characteristic eggs (oval, operculated, approximately 60 μm across) or proglottids provides the diagnosis. The parasite produces nearly 1 million eggs per day, and ova usually are detected easily by fecal examination.

Treatment and Prevention

Treatment with praziquantel (5 to 10 mg/kg as a single oral dose) is highly effective. An alternative medical treatment is niclosamide (50 mg/kg as a single oral dose). Tapeworm-related anemia is reversible by treatment of the infection, but the affected child should receive supplementation with vitamin B₁₂ initially.

A significant reduction in the transmission of *D. latum* has been accomplished in many areas through the introduction of sewage treatment and targeted drug treatment of human infections. Raw and undercooked fresh or chilled fish should not be consumed in areas where a possibility of larval infection exists. Also, caution should be used when consuming raw fresh or chilled imported farmed fish from endemic countries.²⁴⁷ Larvae do not survive in fish that either is cooked for 5 minutes or more at temperatures of at least 55°C or frozen at temperatures of at least -10°C for 8 to 72 hours.⁶⁸

DIPYLIDIUM CANINUM (DOG TAPEWORM)

Dipylidium caninum, the common tapeworm of dogs and cats, also infects infants and young children.^{46,312} Transmission occurs through the accidental ingestion of infected dog, cat, or human fleas (*Ctenocephalides* spp.) and less often body lice (*Trichodectes* spp.). Although it usually is asymptomatic, infection may be associated with decreased appetite, abdominal discomfort, or, perhaps, diarrhea.

Organism

D. caninum adult worms have a scolex with four cup-shaped suckers and a rostellum that bears one to seven rows of small hooks. The worm ranges from 10 to 50 cm in length. The gravid proglottids resemble cucumber seeds in size and shape. The proglottids have two pairs of sex organs, and a genital pore opens on each lateral margin. The eggs measure 35 to 65 μm in diameter and appear in packets of 5 to 30 enclosed in a membrane. The motile gravid proglottids are excreted in feces or migrate actively from the anus. The eggs are liberated as the proglottid disintegrates in the environment. The flea larvae ingest the eggs of *D. caninum*. Development of the tapeworm's larval stages leading to a cysticercoid takes place as the flea metamorphoses into an adult. When the flea is ingested by the definitive host, the adult tapeworm develops in the small intestine.

Transmission and Epidemiology

Humans acquire the infection by the accidental ingestion of infected fleas. Because of the motility of the proglottids, eggs may be disseminated widely in the environment. Fleas are so ubiquitous that transmission to the intermediate host is accomplished readily.

Infection of dogs and cats is a common occurrence worldwide. *D. caninum* also has been found in a variety of wild canines and felids. Reports of dipylidiasis in humans in the United States, however, are uncommon and include almost exclusively infants.^{33,179}

Clinical Manifestations, Diagnosis, Prognosis, and Treatment

Although the incubation period in humans is unknown, infection has been seen in infants aged 5 weeks. Frequently, the only evidence of infection is the finding of proglottids in stool or in an infant's diapers. Varying degrees of abdominal pain, diarrhea, irritability, and even pruritus have been recorded in symptomatic children.

The characteristic proglottids must be differentiated from other parasites. A frequent error is to assume, from the parents' description,

that the small, motile proglottids that migrate from the anus are pinworms or fly larvae.²⁴⁶ Examination of stool specimens may be spuriously negative because proglottids tend to migrate from the fecal mass and disintegrate on the walls of the specimen container. Treatment with praziquantel 5 to 10 mg/kg as a single oral dose is effective. An alternative treatment is niclosamide 50 mg/kg as a single oral dose.

Infected dogs and cats also should be treated. Flea control requires the use of appropriate insecticides on pets. In addition, particular attention must be given to carpets and areas where pets sleep because these are the sites of development of the larval fleas.

HYMENOLEPIS NANA (DWARF TAPEWORM)

Infection with *Hymenolepis nana*, the dwarf tapeworm, occurs worldwide and probably is maintained by direct fecal-oral transmission from person to person.^{46,312,323} Insects may serve as intermediate hosts. Infection may be asymptomatic, but gastrointestinal, neurologic, and allergic symptoms have been reported.

Organism

Adult worms of *H. nana* measure 1 to 5 cm in length and are less than 1 mm in width. The tiny scolex has four cup-shaped suckers and a rostellum with a circle of 20 to 30 small hooks. Gravid proglottids disintegrate within the intestine, and eggs are found in the feces. The oval eggs measure 30 to 50 μm in diameter and contain a six-hooked embryo within two envelopes. The space between the two envelopes contains filaments that extend from two small polar protrusions on the inner envelope. Larval stages develop in insect intermediate hosts after they have ingested the eggs. However, if the definitive host ingests eggs, larval stages invade the intestinal villi and develop a cysticercoid larva in 4 to 5 days. Then larvae break into the lumen and develop into adult worms. Ova appear in feces 2 to 4 weeks after infection occurs. Autoinfection with *H. nana* causes long-term infections and occurs when eggs hatch in the intestinal lumen and larvae go through the rest of the lifecycle without ever being shed in to the environment. A morphologically identical organism found in rodents may be a separate species. The rodent strains are alternatively called *Hymenolepis fraterna* or *H. nana* var. *fraterna*.^{46,166} The rodent strain occasionally infects humans.

Transmission

Human infection is acquired most commonly by the ingestion of eggs from the feces of infected persons or by autoinfection. Humans serve as both intermediate and definitive hosts in this direct cycle. Poor hygienic habits, overcrowding, lack of running water, and poor management of human excreta enhance transmission through the fecal-oral route. The rodent strains of *H. nana* are infectious for humans, and food contaminated by rodent feces is a possible source of infection. Eggs may be produced for periods longer than 1 year, but the possibility of recurrent autoinfection obscures the determination of the duration of the initial infection.

Epidemiology

H. nana is a common parasite of rats and mice worldwide, and 50 to 75 million people are thought to be infected.^{46,312} The distribution of infection in humans is worldwide, with an increased prevalence in some urban areas. Stool surveys from endemic areas commonly show prevalence rates of 5% to 25%, which may approach 50% in children aged 4 to 10 years.⁵⁰ Children in slums and refugee camps are at high risk for infection.^{1,176} In the United States, 1.5% of stool samples of subjects with gastrointestinal symptoms harbored *H. nana* eggs in the Rocky Mountain region.⁴¹ Older reports showed a prevalence of up to 15% in institutionalized individuals in New York.³¹⁶

Pathology and Pathogenesis

Little is known of the pathogenesis and pathology of *H. nana* infection in humans. The larval stage of *H. nana* is a cystlike structure called a *cysticercoid* that is approximately 250 μm in diameter. Local reactions consisting of mucosal inflammation or atrophy may occur at the site of attachment of the adult worms in the small intestine. Rare cases of

disseminated infection in children and adults with depressed cellular immunity have been reported.^{163,183}

Clinical Manifestations

A wide variety of symptoms have been ascribed to *H. nana* infection, but few well-controlled clinical studies have been presented. However, a significant number of cross-sectional studies suggest an increased prevalence of diarrhea in children with hymenolepiasis.^{1,176,235,280,323} Heavy burdens of worms have been associated with abdominal pain, malnutrition, retardation of growth, and lethargy, whereas children with low burdens did not have significant symptoms.^{36,37,270} In addition, a few studies have associated *H. nana* infection and anemia in children.^{176,309}

Diagnosis

Detection of the characteristic eggs in fecal material by examination of direct saline wet mounts or by concentration techniques usually is not difficult. However, a single examination is not always adequate to rule out infection.

Treatment and Prognosis

Praziquantel 25 mg/kg as a single oral dose is effective in treating *H. nana* infection. However, under some conditions a second dose at least 10 days apart may be recommended to prevent relapses because praziquantel is less effective against the cysticercoid stage *H. nana*.⁵¹ Nitazoxanide 100 mg by mouth twice daily for 3 days for children 1 to 3 years of age, 200 mg by mouth twice daily for 3 days for children 4 to 11 years of age, and 500 mg by mouth twice daily for 3 days for older children is a reasonable alternative therapy; efficacy is approximately 75% to 82%.^{36,202} Family members should be examined and treated if they are infected. Infection with *H. nana* rarely is severe and responds well to appropriate treatment.

Prevention

Transmission of *H. nana* infection could be prevented by treating infected subjects, improving personal hygiene, promoting the consumption of safe water, and disposal of human waste. Infected food handlers always should be treated and monitored to ensure that treatment has been successful. Stored food should be protected from rodents and insects.

HYMENOLEPIS DIMINUTA (RAT TAPEWORM)

Hymenolepis diminuta is a rat tapeworm that only rarely presents as a human infection. Adult worms are 20 to 90 cm long, and the eggs are round.^{46,312} Children become infected after ingesting larva-infected insects. Infection often is asymptomatic, but abdominal discomfort and pruritus have been reported. Treatment is with praziquantel 25 mg/kg in a single oral dose or niclosamide.

SPARGANOSIS (INTERMEDIATE-STAGE SPIROMETRA SPECIES INFECTION)

Sparganosis is a zoonotic infection seen most frequently in eastern Asia.^{119,161,312} Recent cases have been recognized from Africa.⁷⁰ It occurs when humans are infected with a metacystode larval stage of *Spirometra* spp. and is often caused by *Spirometra erinaceieuropaei* in Asia and *Spirometra mansonioides* in the Americas.⁸

Organism

Evidence indicates that the amorphous, thin, ribbon-like *Spargana* organisms recovered from human infections belong to the genus *Spirometra*.^{119,312} The adult tapeworms are found in dogs, cats, and a variety of wild carnivores. Eggs passed in the feces of these definitive hosts hatch in fresh water. The embryo that emerges from the egg is ingested by a copepod, where it undergoes larval development as a proceroid. When a second intermediate host ingests the infected copepod, the larva develops into a sparganum (plerocercoid). The range of second intermediate hosts includes amphibians, reptiles, birds, and mammals. When the second intermediate host is eaten by the definitive host, the sparganum attaches to the intestinal mucosa and develops into the

adult tapeworm. A rare form of sparganosis that buds, branches, and multiplies asexually to massive numbers in humans is called *Sparganum proliferum*.¹⁸⁵

Transmission

Sparganosis can be acquired by ingestion of copepods infected with proceroids or fish, reptiles, or frogs containing plerocercoids. In parts of Asia, application of poultices of amphibian or reptile flesh to wounds or sores is a common practice, and children can be infected when the *Spargana* organisms migrate from the poultice into human tissues. Human sparganosis in the United States often is associated with drinking well water or untreated surface water that could contain the minute copepods containing the proceroid form. Transmission by ingestion of the raw or inadequately cooked flesh of second intermediate hosts has been demonstrated experimentally in humans. Animal sources such as snakes, frogs, chickens, and pigs have been incriminated in human infection. Asymptomatic cats, especially those living outdoors, are infected in some areas.^{123,135,242}

Epidemiology

Human infection is not uncommon in Thailand.¹⁶¹ It is also reported from China, Korea, Japan, India, Indonesia, the Philippines, Australia, Africa, Italy, South America, and the former Soviet Union.^{119,159,312,313} With changes in lifestyle and environmental control, the rate of sparganum seropositivity among patients suspected of having parasitic disease in South Korea dropped from 2.6% in 1993 to 1.6% in 2006.¹⁵⁴ However, the infection still seems to be a bit less uncommon in North Korea.²⁶² In the United States, almost all reports have come from the southern or southeastern states and from Puerto Rico or were reported in persons who had been in these areas, but one infected child was reported from southern California.⁴⁴

Pathology, Pathogenesis, and Clinical Manifestations

Ocular sparganosis, usually acquired by contact, may involve conjunctival, retroorbital, or palpebral tissues and cause conjunctivitis, periorbital and palpebral edema, exophthalmos, chemosis, and corneal ulceration.^{119,312,313} Subcutaneous sparganosis is the most common form of the infection, with the trunk frequently being involved. The lesion usually is nodular. Tenderness and inflammation may be absent, intermittent, or constant. Some lesions are migratory. Eosinophils may or may not be present. Some infections have had an associated peripheral eosinophilia, but it is not a constant finding. *Spargana* have been identified in a wide range of other tissues. Sparganosis of the CNS may be associated with a variety of neurologic manifestations.^{119,149,273,312,313} Brain imaging of patients with cerebral sparganosis shows edema and degeneration of cerebral white matter commonly with a "tunnel sign" of hypodensity and ring enhancement.²⁷³ Sequential MRI has revealed migration of larva between various regions of the brain in some children.^{16,111} The disease caused by *S. proliferum* consists of progressive replacement of host tissues by the multiplying organisms.

Diagnosis

The diagnosis may be suspected in persons with typical subcutaneous lesions and a suggestive epidemiologic background. Usually, however, the diagnosis is made during surgical removal of a painful or cosmetically disturbing lump without anticipation of the parasitic etiology. *Spargana* organisms vary considerably in width and length. They usually are several centimeters in length, whitish, and opaque, and they may have the grooved indentations on the anterior end that are precursors of the bothria, or suckers of the scolex, of the adult worm. Small portions of *Spargana* are difficult to distinguish grossly or microscopically from cysticerci and other less common larval cestodes. Neuroimaging may yield characteristic findings in cerebral sparganosis.^{149,273} Performing an ELISA or serum and CSF antibody appears to be useful in endemic areas, but this test is not generally available.³¹²

Treatment and Prevention

Surgical removal is the only known form of therapy. Stereotactic aspiration and microsurgery have been effective, but care to remove all larval material is essential.⁶² Praziquantel has been used in some cases, but

no convincing evidence of clinical activity exists. Filtration of water prevents the ingestion of copepods from wells or ponds. Proper cooking of meat eliminates second intermediate hosts as sources of infection. Educational effort should be made to warn of the dangers of applying raw flesh poultices in areas where it is a cultural practice.

ECHINOCOCCUS GRANULOSUS AND RELATED SPECIES (CYSTIC HYDATID DISEASE)

Humans may be infected with the larval stages of parasites of the genus *Echinococcus*.^{18,19,47,48,71,72,136,251,325} The infection is acquired by the ingestion of ova from the feces of carnivorous definitive hosts. The disease in humans and other intermediate hosts is called hydatid disease and is characterized further according to the morphologic features of each species larval stage: cystic echinococcosis caused by *Echinococcus granulosus* sensu stricto and related organisms, alveolar echinococcosis caused by *Echinococcus multilocularis*, and polycystic echinococcosis caused by *Echinococcus vogeli* or *Echinococcus oligarthrus*. The prevalence of hydatid disease is markedly higher in adults than in children, and most pediatric cases present with cystic echinococcosis, which is the focus of this section of the chapter.^{18,47,48,71,72,136,251}

Organisms

Cystic echinococcosis is caused by *E. granulosus* sensu lato. Genetic studies have demonstrated 10 separate genotypes grouped into different clusters that infect different intermediate and definitive hosts.^{71,136,251,288,325} Significantly different strains are found in sheep, Tasmanian sheep, cattle, pigs, horses, camels, and cervids (e.g., deer, reindeer, moose, elk). Thus the genotypic clusters include *E. granulosus* sensu stricto (genotypes 1–3), *E. equinus* (genotype 4), *E. ortleppi* (genotype 5), and *E. canadensis* (genotypes 6–10).⁶ Most human infections are caused by *E. granulosus* sensu stricto genotype 1 (the sheep strain). *E. ortleppi* and *E. canadensis* have been reported to infect humans, with *E. canadensis* genotype 6 being the second most common genotype to infect humans. *E. equinus* is regarded as not infective to humans, and no cases have been reported.⁶ The life cycles of the species of *Echinococcus* are similar, but the geographic distributions, types of hosts, and clinical and morphologic features of the parasites differ significantly. Adult tapeworms of *E. granulosus* sensu stricto are found in dogs. *E. canadensis* tapeworms infect primarily wolves, but dogs also may be infected. The adult tapeworm is only 3 to 8 mm long and has two to five segments. Dogs often are hosts to thousands of adult worms. When sheep or humans ingest eggs from the feces of infected dogs, the embryos hatch in the intestine and burrow through the intestinal wall to gain access to the portal circulation. The embryos that survive are able to develop in many tissues, but they do so most commonly in the liver or lungs, where they become the cystic larval structures called *hydatid cysts*. A hydatid cyst is composed of an outer laminated, acellular membrane that is lined by a thin, cellular germinal membrane. Spherical structures called *brood capsules* grow from the germinal membrane. Protoscolices develop within the brood capsules. Each protoscolex has suckers and hooks and the potential to become the scolex of an adult worm if it is eaten by a dog. Compression and reaction from growth of the cyst produce a “pericyst” of compact, collagen-rich host tissue around its exterior. In older cysts, so-called daughter cysts may develop within the primary cyst cavity.

Transmission

Humans acquire cystic hydatid disease by ingestion of ova shed by the definite host, typically dogs.^{48,71,173,181,243,251} Close contact with dogs can result in infection because tapeworm eggs can be found on the dog’s perianal hair, muzzle, and paws. Contaminated food, drink, or fomites (e.g., flies and other insects) may disseminate the eggs from dogs’ feces. However, most cases occur in pastoral families and are associated with close contact with infected dogs.

Epidemiology

E. granulosus sensu stricto is found worldwide in most areas where sheep are raised.^{18,48,71,136,173,181,251} Studies of the global burden of disease and economic impact of cystic hydatid disease suggest that the

impact is significantly underestimated in contrast to other illnesses.²⁰ The disease is endemic in the sheep-raising areas of South America, the Middle East, the Mediterranean basin, China, and the former Soviet Union.^{21,48,71,136,173,181,243,251} One of the highest morbidity rates is seen in rural Africans in Kenya and Uganda, where people live in close association with their dogs. The custom of feeding sheep viscera to sheepdogs maintains foci of infection. Up to 79% of stray dogs were tapeworm carriers in one study in Peru, and 100% of sheepdogs were infected in study from Libya.^{25,162} In the United States, Basques in central California, Mormon ranchers in Utah, and Native Americans in Arizona and New Mexico have been infected. In Alaska and Canada, human infection usually is limited to Eskimos and Native Americans who have working dogs that are fed moose and reindeer viscera.²⁹¹ The strain found in this region often is manifested as giant pulmonary cysts.

Pathology and Pathogenesis

In cystic hydatid disease, the pathologic process is related to compression or displacement of the host’s tissue.^{71,207,251} Cyst growth is variable and depends on (1) the organism involved being slower in the liver than in the lung; (2) the *Echinococcus* species, with *E. canadensis* usually being slow growing; and (3) the age of the subject, with cyst growth being faster in younger individuals.²³⁶ Rates of up to 4 to 5 cm per year have been reported, but growth may be more rapid in the lung. The cyst may exceed 35 cm in diameter in the abdominal cavity. When rupture or leakage of a cyst occurs, an allergic reaction caused by the antigenic cyst contents may develop. Cysts may calcify after many years, which usually signifies death of the parasite. Hydatid cysts may form foci for secondary bacterial infection causing liver and lung abscesses.

Clinical Manifestations

Most children with *E. granulosus* infection have a single unilocular cyst, but multiple cysts are seen in 15% to 30% of patients, usually in a single organ system.^{71,207,251,325} The most common site of the cysts is in the liver. In clinical series, approximately one in five children with a pulmonary cyst also has a concurrent liver cyst, but the proportion outside the liver is lower in population-based screening.⁶⁰ Approximately 10% of cysts are found in sites other than the liver or lung, including the spleen, kidney, peritoneum, genitourinary tract, bone, muscles, heart, eye, and brain. *E. canadensis* in Canada and Alaska characteristically produces slowly growing pulmonary cysts.^{71,207,251} CNS hydatid disease occurs much more commonly in children than in adults.^{43,66,67,146,178,196} Bone cysts, which may be seen in preschool children, occur most frequently in vertebral and long bones.^{207,251} Unlike cysts in other sites, bone cysts characteristically are multilocular and contain little fluid. Eye, bone, and brain cysts typically are small when they are discovered, whereas cysts in other sites may exceed 35 cm in diameter before being detected. Complications usually occur only if cysts become large, and compress or erode into adjacent structures. Cyst leakage or rupture is one of the most common complications and may result in seeding of body cavities with fertile protoscolices, local inflammatory reactions (e.g., pneumonitis), infection of the cyst cavity, and type 1 allergic reactions, including hypotension, urticaria, and eosinophilia. Rupture may occur spontaneously or secondary to trauma or surgery, but it generally is considered to be an uncommon complication of hydatid disease in children.

The wide spectrum of symptoms in cystic hydatid disease depends on the number, size, and location of the cysts.^{71,207,251} Slowly growing cysts in liver or lung often are asymptomatic for years. Symptomatic intrahepatic cysts cause constant or intermittent right upper quadrant or epigastric pain, enlargement of the liver, or nausea and vomiting. Unruptured cysts rarely cause fever. Rupture of a cyst may be precipitated by a traumatic event and may cause a range of symptoms, including fever, abdominal pain, hypotension, and allergic manifestations, including eosinophilia, urticaria, and anaphylaxis. Rupture into the biliary tract may cause cholangitis with fever and right upper quadrant pain. Some children with hydatid disease also have retarded growth patterns.¹⁷²

Intact pulmonary cysts typically do not cause symptoms.^{71,207,251,261,295} Rupture or leakage, however, may cause cough, chest pain, dyspnea, hemoptysis, and a salty taste. Fever may be present, but it is often a

marker for secondary bacterial infection. As many as one-third of pulmonary cysts rupture into the pleural space or into a bronchus. In the latter case, the patient may describe coughing up portions of the membranes, which may resemble grape skins, or noting a characteristic salty taste. Bone cysts are seen in patients with bone pain or pathologic fracture. Vertebral hydatid disease causes signs and symptoms of spinal cord and radicular compression; severe pain on palpation of the affected portion of the spine is characteristic. Of intracranial cysts, 50% to 75% are seen in children.^{43,109,146,299} Increased intracranial pressure with headache, vomiting, and focal neurologic symptoms are common findings. Seizures also may occur.

Diagnosis

The diagnosis of cystic echinococcosis usually is suspected on the basis of clinical or radiologic findings plus a history of residence in an endemic area.^{18–20} Physical examination rarely is definitive. Only half of patients with hepatic cysts have abnormal liver enzyme results. Eosinophilia typically is low grade or absent. The initial diagnosis of cystic hydatid disease often is based on imaging findings. An unruptured pulmonary hydatid cyst has a sharply demarcated, round or oval smooth border. In the lung, it has a homogeneous cannonball appearance and sometimes is surrounded by a layer of atelectatic lung.^{71,207,251} After the cyst has ruptured into a bronchus, a crescent-shaped air layer may be seen that is virtually diagnostic. In addition to the arc of air between the parasite and the host cyst wall, air in the cyst lumen also may be present. The membrane of a collapsed cyst floating on the surface of the fluid in a ruptured pulmonary cyst has a characteristic “water lily” appearance.

Cysts in the liver usually are visualized easily and measured with ultrasonography, CT, or MRI. Ultrasound techniques are useful for defining most cysts within the abdomen and can differentiate fluid-filled cysts from solid tumors. Because ultrasonography is portable and relatively inexpensive, it has been the main technique used in epidemiologic studies and clinical cases in developing countries. A World Health Organization staging system has been developed to define management (Fig. 227.4).^{9,234} Stage CL cysts are unilocular collections without a discrete wall and with uniform anechoic contents. This appearance is not specific for *Echinococcus*. Stage CE1 cysts have a dense wall and may have internal echoes. This so-called hydatid sand is caused by protoscolices within the cyst. CE2 cysts have internal septa or daughter cysts, forming honeycomb patterns that are highly characteristic of hydatid cysts. CE3 cysts may demonstrate detachment of the cyst wall or early collapse (CE3a) or a mixed image with defined cystic and solid lesions (CE3b). CE4 cysts demonstrate inhomogeneous material instead of a cyst cavity sometimes showing collapsed membranes. CE5 cysts

demonstrate a thick rim of calcification. Radiographically apparent cyst wall calcification occurs only in liver or spleen cysts and generally takes more than 5 to 10 years to develop. Bone cysts typically produce radiolucencies without periosteal reaction. MRI offers little advantage over CT for the imaging of cysts except in the CNS and for demonstration of biliary fistulas.¹²⁶

Fine-needle aspiration of cysts for establishment of the diagnosis can cause spillage of hydatid fluid, which may induce anaphylactic shock and possibly secondary cyst development. The percutaneous route has been used for both diagnosis and treatment, with few untoward events. A review of 765 PAIR (percutaneous aspiration, introduction of scolicide, and reaspiration) procedures showed that anaphylaxis and spillage occurred in 0.5% in each case. However, 14% of the subjects had other complications that included fever, abscesses, and biliary fistulas.⁷⁷ The fluid obtained should be examined for evidence of protoscolices, hooks, or antigen.

Serologic tests can be useful in confirmation of the diagnosis.^{71,207,251} Antibody tests using crude antigen of either *E. granulosus* or *E. multilocularis* tested by ELISA, indirect hemagglutination, and fluorescent antibody assays are positive in 50% to 90% of cases. False-negative results are more common in patients with pulmonary, brain, and splenic cysts. Commercial rapid tests for the detection of *Echinococcus* antibodies are available, but their sensitivity and specificity are low, especially in subjects with inactive liver cysts.²⁸³ Because the tests available may cross-react with cysticercosis or other parasitic infections, positive results should be confirmed by a more specific test, either an immunoblot assay or a gel diffusion assay.

Treatment and Prognosis

The treatment of cystic echinococcosis is in evolution.^{19,20,325} Surgery was the traditional treatment of choice for nearly all cases of cystic echinococcosis, but a range of different approaches have been accepted gradually, including surgery, antiparasitic chemotherapy, percutaneous drainage (e.g., PAIR), and “watch and wait.”^{20,208,229} Currently expert opinion suggests that treatment should vary on the basis of the location of the cyst or cysts, the nature and size of the cysts, the condition of the patient, and the available expertise, with surgery required by only a minority of cases. A conservative management (watch-and-wait approach) with regular follow-up of the patients is acceptable under some circumstance. For example, in a prospective study, only 10% of children with hepatic cysts detected in a population-based ultrasound survey required surgery during the subsequent 5 years.^{60,152} In a cohort of subjects diagnosed with 47 inactive liver cysts (CE4 and CE5) managed with a watch-and-wait approach and followed for a median of 52 months,

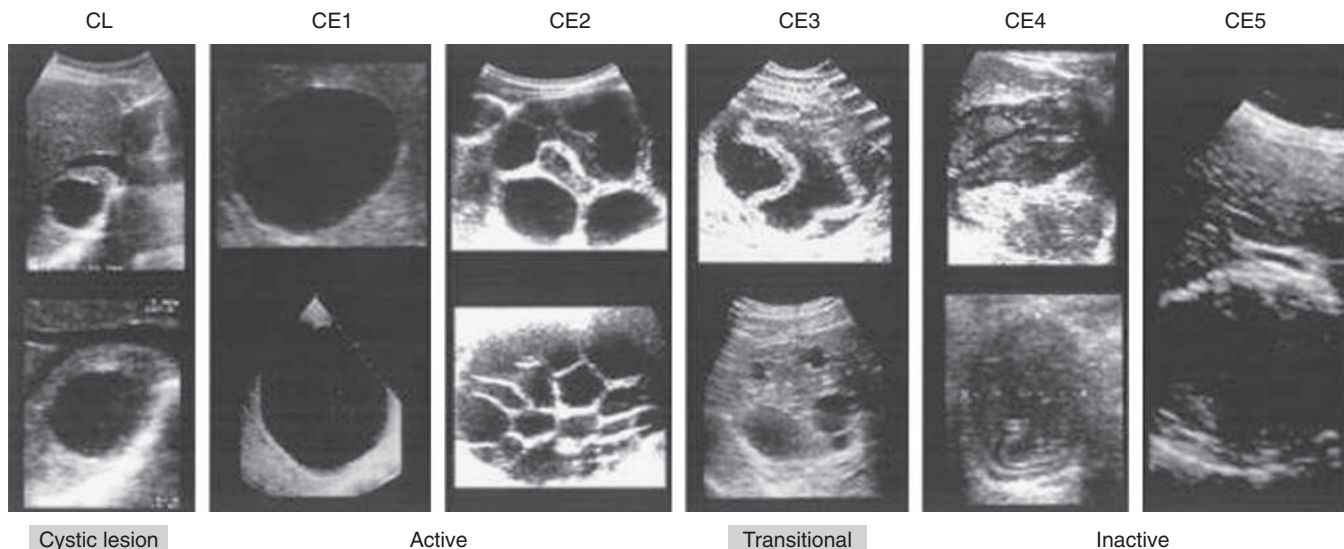

FIG. 227.4 Staging of echinococcosis. (Courtesy World Health Organization Informal Working Group on Echinococcosis: international classification of ultrasound images of cystic echinococcosis.)

only 1 case reactivated during the observation period.²⁰⁸ The watch-and-wait approach was compared with albendazole treatment for 27 liver CE3b cysts. Although subjects treated with albendazole reached an inactive cyst stage faster than untreated subjects, the time to relapse of the cystic lesions was not different between the groups.²²⁹

The benzimidazoles albendazole and mebendazole have been used for chemotherapy.^{71,76,80,145,152,251,278,294} Approximately one-third of hepatic cysts will resolve in response to benzimidazoles, and 30% to 50% will improve. Many of the residual cystic lesions considered treatment failures were shown subsequently to be inactive. The response to chemotherapy is better with smaller lesions. It is now thought to be the treatment of choice for small (<5 cm) CE1 and perhaps CE3a lesions.^{20,71,251} Chemotherapy also has proved to be successful for treatment of small pulmonary cysts.⁶⁵ However, a high failure rate exists with chemotherapy alone for larger lesions in either the liver or the lung.²⁰ Albendazole is thought to be more effective than mebendazole. Albendazole typically is dosed at 10 to 15 mg/kg per day in two daily doses continued for 3 to 6 months. Side effects may include neutropenia, elevated liver enzymes, and alopecia. Prospective studies of surgically removed specimens show that protoscolices can remain viable for as long as 3 months, which is the minimum duration of chemotherapy.^{15,76} Treatment failures have been successfully managed by further chemotherapy, PAIR, or surgery. In some cases, PAIR may demonstrate that protoscolices no longer are viable, even with persistent lesions. Because chemotherapy can be associated with relapses or treatment failure, children should receive follow-up imaging studies every 6 to 12 months for years after receiving chemotherapy. Chemotherapy also is an important adjunct to surgical therapy.

The PAIR technique offers a less invasive option than the traditional surgical approaches.^{20,21,77,148,192,251,272,314,315} Results have been similar to those with surgery, but with fewer perioperative complications. PAIR is thought to be the treatment of choice for uncomplicated CE1 lesions larger than 5 cm and CE3a lesions. CE2 lesions can be treated with a modification of PAIR that employs a larger bore catheter and drainage combined with albendazole.^{21,255} The treatment of CE3b lesions is usually surgical unless there is a reason precluding an invasive approach, in which case the watch-and-wait approach may be used. Although the data comparing different treatments are limited, PAIR was associated with similar efficacy and less morbidity than surgery in one randomized trial. PAIR should be performed after initiation of albendazole chemotherapy for at least 4 hours but preferably for several days. In a controlled trial, PAIR plus chemotherapy was superior to either chemotherapy or PAIR alone.^{147,192} Aspiration generally should go through solid tissue (e.g., liver) rather than directly into the cyst (to limit spillage). The cyst fluid should be examined for protoscolices or hooks (to confirm the diagnosis). Before scolical agents are injected, the cyst fluid should be checked for bilirubin by dipstick, which suggests the presence of a biliary fistula. Injection of contrast medium to further characterize the biliary tract communication is necessary in positive cases because scolical agents can cause sclerosing cholangitis if they are injected into the biliary tract. Alcohol and hypertonic saline have been used as scolical agents in this procedure. Contrast material also is mildly scolical. Contraindications to PAIR include communication with the biliary tract, inaccessibility, superficial cysts, and cysts that are free in the abdomen, heart, brain, or spine.

Surgery has been the traditional approach to therapy for hydatid disease and remains the treatment of choice for complicated infections, lung lesions, and CE3b lesions.^{20,71,207,251} The goal of surgery is to remove the entire cyst without spilling its contents. Rupture of the cyst contents at the time of surgery carries a risk for causing disseminated echinococcosis and a small risk for anaphylaxis occurring at the time of operation. Surgical approaches have included pericystectomy (removal of the entire cyst and a rim of surrounding tissues), resection of the involved organ, simple drainage, omentoplasty, and capitonnage. In general, the more radical procedures have been associated with fewer relapses, but at the cost of more perioperative complications. However, laparoscopic approaches have been reported recently to be associated with a high success rate and less morbidity.^{26,69,165,315} Chemotherapy with albendazole with or without praziquantel is performed routinely.^{12,76,251} With administration of chemotherapy, pressure within the cyst may be reduced,

and removal of cyst membranes and contents will be facilitated. In addition, treatment decreases the likelihood of development of secondary cysts. With albendazole alone, cysts remain viable for as long as 3 months.¹⁵ The preoperative administration of praziquantel combined with a benzimidazole has been suggested because of the scolical properties of praziquantel.¹² The practice of injecting the cyst with scolical drugs before removing it is associated with complications and is not thought to be necessary in the setting of preoperative and postoperative chemotherapy.²⁵¹

Pulmonary cysts have been treated successfully surgically, medically, and with PAIR.^{2,20,65,143,170,271} No controlled trials of these different strategies have been performed. However, retrospective series suggest that smaller cysts often respond to antiparasitic chemotherapy.⁶⁵ Larger cysts may be treated with surgery. *E. canadensis* from Alaska and Canada do not produce anaphylaxis on rupture, and pulmonary cysts spontaneously resolve after evacuating into bronchi. If the cyst wall remains in place after the patient has undergone chemotherapy or PAIR, residual parasite material can serve as a nidus for bacterial superinfections.²⁰⁶ Thus many experts recommend against PAIR for pulmonary disease.²⁰

The prognosis of hydatid disease varies widely from self-limited asymptomatic infection to fatal infection associated with rupture of the cyst. All of the modes of therapy are associated with relapse during the first few years of treatment. Thus careful follow-up is essential. With appropriate therapy, however, few cases are fatal.

Prevention

Control programs for cystic hydatid disease have met with variable success.^{46,47,251} *E. granulosus* was eliminated from Iceland by banning home slaughter of sheep. Banning of home slaughter, education, arecoline purging of dogs, and treatment of infected dogs with praziquantel led to eradication in New Zealand and Tasmania. However, these eradication programs required significant resources and have been less successful elsewhere. A recombinant vaccine has proved to be highly effective in field studies but awaits implementation.⁴⁷ Other tools in developmental stages include coproantigen tests to detect infected dogs and improved therapy for ovine infection.

OTHER ECHINOCOCCUS SPECIES

Echinococcus multilocularis is the cause of alveolar hydatid disease.^{71,136,144,207,251} Humans are an incidental host in a life cycle that typically involves foxes as definitive hosts (but also wolves and occasionally domestic dogs) and rodents as intermediate hosts. The larval parasite does not form a large cystic structure but grows by progressive external budding. The laminated membrane and host pericyst are thin. The larval mass slowly enlarges and replaces liver tissue much as a malignant neoplasm does. *E. multilocularis* is endemic in arctic and alpine areas, including western China, central Europe, and scattered foci in North America. In recent years, disease is emerging in much of central Europe. The larvae may invade contiguous structures and rarely metastasize. Human infection almost invariably involves the liver, but it may spread to adjacent tissues or metastasize to the brain. Because the larval mass grows slowly, with a typical latent period of 5 to 15 years before clinical presentation, clinical disease is a rare finding in children. Diagnosis involves imaging studies with serologic confirmation. Management requires surgical resection along with prolonged chemotherapy. Comprehensive reviews of epidemiology, clinical manifestations, diagnosis, and management are available.^{17,71,136,144,207,251}

E. vogeli is a parasite of bush dogs and feral dogs in South America.²⁵¹ The intermediate hosts are rodents (i.e., pacas, agoutis, spiny rats). When humans are infected, the germinal membrane grows externally to form additional cysts, and septa develop within the original cyst. This manifestation is the "polycystic" variety of hydatid disease. A rare polycystic hydatid disease in humans has been attributed to *E. oligarthrus*, a fourth species that is found as adult tapeworms in wild felids such as pumas and jaguars. The intermediate hosts are the same as those for *E. vogeli*. Most infections occur in Central and South America. Polycystic hydatid disease is limited to South and Central America, where fewer than 100 human infections have been reported. Initial management should include administration of albendazole.

Foodborne Trematodes

Miguel M. Cabada • Philip R. Fischer • A. Clinton White Jr

An estimated 56 million people are infected with foodborne trematodes, referred to as flukes. Almost 8 million have heavy infections.⁴² Approximately 10% of the world's population is at risk for acquiring a trematode infection.

Flukes are flatworms (members of the phylum Platyhelminthes and of the subphylum Trematoda) (Figs. 228.1 to 228.3).^{58,75,103} The adult forms of foodborne trematodes are flat and leaf shaped, with an oral and a ventral sucker for feeding and attachment, respectively, and a bifurcated, blind-ended gastrointestinal tract. Foodborne trematodes are hermaphroditic, producing operculated eggs that typically are passed in host feces. Eggs possess an operculum at one end, the opening through which a ciliated larva or miracidium will hatch. Specific species of freshwater snails are intermediate hosts for trematodes and are infected by either direct penetration by the ciliated larva or by ingestion of the unhatched egg. Complex larval development and multiplication occur within the snail host, with large numbers of larvae called cercariae ultimately produced. In most trematode life cycles, the cercariae emerge from the snails and swim about until they are ingested by or attach to the second intermediate host, which may be fish, crustaceans, mollusks, or aquatic vegetation. After attachment occurs, the larvae develop into metacercariae within protective cyst walls. Humans are typically infected by ingestion of the metacercariae. In Southeast Asia and the western Pacific region, foodborne trematodiasis has become an emerging public health problem, associated with the growth of aquaculture.^{41,57} Many of the medically important flukes have a wide range of definitive hosts. Diagnosis of fluke infections typically is accomplished by examination of fecal specimens (or sputum in the case of *Paragonimus* spp.) for characteristic ova. Immunodiagnostic tests are available to aid in establishing the diagnosis of some flukes and are becoming the preferred method of diagnosis for certain species. Common liver, intestinal, and lung flukes are reviewed in this chapter.

LIVER FLUKES

Clonorchiasis and Opisthorchiasis

Three similar trematodes of the genus *Opisthorchis* infect the bile ducts of humans.^{41,43,58,75} Although the name *Opisthorchis sinensis* is proper parasitologically, this organism is commonly referred to as *Clonorchis sinensis*, and the name of the infection, clonorchiasis, is well entrenched in the clinical literature. *Opisthorchis viverrini* and *Opisthorchis felinus* have similar life cycles and produce similar lesions and illnesses in humans.

Organisms

The adult flukes measure 4 to 25 mm in length and 2 to 5 mm in breadth and have an anterior oral sucker. The life cycle involves primarily humans, but dogs and cats also act as definitive hosts. Freshwater snails and fish participate as first and second intermediate hosts. In the definitive hosts, parasites are found mainly in the intrahepatic biliary ducts and occasionally in the extrahepatic and pancreatic ducts. *Opisthorchis* spp. and *Clonorchis* spp. produce small operculated eggs ($30 \times 16 \mu\text{m}$), which are nearly identical morphologically. The ova are shed into bile and excreted in feces. The snail host ingests the embryonated eggs, and after a complex cycle of asexual reproduction, free-swimming cercariae emerge 6 to 8 weeks later. The cercariae encyst under the scales or in the muscle of freshwater fish as metacercariae. Humans and other definitive hosts are infected by ingestion of raw, inadequately cooked, or pickled fish infected

with metacercariae. The larvae excyst in the intestine and migrate to the intrahepatic bile ducts through the ampulla of Vater. Juvenile flukes travel along the biliary tree against bile flow and attach to the bile duct epithelium with their suckers. Adult worms begin producing eggs approximately 4 weeks after ingestion and can survive for as long as 30 years.

Transmission and Epidemiology

Transmission is through the ingestion of raw or inadequately cooked freshwater fish infected with metacercariae. Cats, dogs, civet cats, and other fish-eating mammals serve as definitive hosts in nature. The expansion of aquaculture in China and other Asian countries and poor sanitation practices allow the contact of human feces with snails in ponds where fish are raised. This situation increases the risk for parasite transmission and hinders control efforts.^{38,46}

An estimated 600 million people are at risk for *O. sinensis* infection, 67 million for *O. viverrini*, and 12 million for *O. felinus*.⁴² *O. sinensis* is endemic in China, Japan, Korea, Taiwan, and Vietnam. Some of the highest infection rates are reported in endemic areas of China (16%) and Vietnam (26%).⁴⁹ *O. viverrini* is endemic to Thailand, Lao People's Democratic Republic, Vietnam, and Cambodia. In northern Thailand, infection rates may reach 60%, and it is estimated that 7 million residents are infected in that area.⁹⁸ *O. felinus* is endemic in central Siberia and in eastern and southeastern Europe. Sporadic infections with *O. felinus* have been reported from several Asian countries. Also, the infection is an emerging problem in Mediterranean countries, especially in Italy, where outbreaks of the disease have been reported among local populations and travelers.^{88,106} Eating habits and snail presence are the major determinants for the geographic distribution of the infection. The three species of *Opisthorchis* follow similar patterns of infection in most areas. The lowest prevalence and intensity of infection is found in the youngest age groups and in women; whereas intensity of egg excretion often increases with age and male gender.⁹⁵ The prevalence peaks in older persons, as shown in studies in China and Korea.^{27,123}

Pathology and Pathogenesis

The epithelium of infected bile ducts reacts with desquamation, adenomatous hyperplasia, and metaplasia of goblet cells, accompanied by an increase in mucus production. The pathogenesis of the hepatobiliary damage may be due to the induction of an immunologic response in the host by mechanical action and secreted products from the flukes. Fibrosis and ductal dilation and obstruction are the consequence of the inflammatory reaction elicited by the parasites. Bile stasis in turn may lead to bacterial cholangitis and further inflammation in the bile ducts. The severity of the changes relates to the intensity of infection, host susceptibility, and number of reinfections. Chronic infection may lead to extensive periportal and periductal fibrosis, a process in which interleukin-6-mediated responses seemed to play a key role.^{101,103,104}

The infection is a significant risk factor for cholangiocarcinoma in endemic areas.^{102,103} Experiments in hamsters have shown that repeated infection with *O. viverrini* induces overproduction of nitric oxide, which may play a significant role in the development of cholangiocarcinoma through oxidative and nitrosyl DNA damage.⁸⁷ In addition, a granulin-like growth factor in excretory and secretory products from *O. viverrini* induces proliferation of fibroblasts.^{71,107} The excretory and secretory products induce the production of retinoblastoma and cyclin D1 proteins in the hamster model, both of which have been implicated in the mechanism of *Opisthorchis*-induced cholangiocarcinoma.¹⁴ *O. viverrini*

Fascioliasis

(*Fasciola hepatica*)

FIG. 228.1 Life cycle of foodborne trematodes including intestinal flukes (*Echinostoma*, *Fasciolopsis*, *Heterophyes*), a liver fluke (*Opisthorchis sinensis*), and a lung fluke (*Paragonimus*). (From Keiser J, Utzinger J. Food-borne trematodiasis. *Clin Micro Rev*. 2009;22:466-483.)

FIG. 228.2 Foodborne trematode ova found in human stool. (Modified from <http://www.dpd.cdc.gov/dpdx/HTML/MorphologyTables.htm>.)

infections involve the gallbladder and may lead to complications such as gallbladder sludge, cholecystitis, and formation of gallstones.^{76,77} The parasites may be found in the pancreatic ducts, where reactions of the epithelium are similar to those in the bile duct. Pancreatitis occurs infrequently in these liver fluke infections and is usually mild.

Clinical Manifestations

In endemic areas, infections may begin early in life and often are asymptomatic.^{77,103} The occurrence of symptoms correlates with the intensity of infection. Patients with higher fluke burdens are more likely than those with lower burdens to have right upper quadrant pain, abdominal discomfort, and jaundice. They are also more likely to have abnormalities on ultrasound examination, such as intrahepatic bile duct dilation and periductal liver fibrosis.⁹⁵ Other findings may include weakness, malaise, and liver enlargement. A community-based study showed significant improvement of symptoms, laboratory test results, and ultrasound abnormalities after treatment of infected subjects.⁸⁹

An acute febrile syndrome starting 2 to 3 weeks after exposure has been reported with *O. sinensis* and *O. felinus* infections.^{43,103} In *O. felinus* outbreaks, up to 80% of those infected may develop acute symptoms of infections and a cholestatic pattern in liver enzymes elevation.¹⁰⁹ The symptoms include fever, malaise, anorexia, diarrhea, and tender hepatomegaly. Eosinophilia, which is not as common in the chronic phase, is typically found during the acute illness.

Complications are more likely to occur in heavy infections. Relapsing cholangitis, cholecystitis, bilirubin gallstones, and pancreatitis all have been associated with infection.^{76,95} Clonorchiasis has been cited as a cause of pancreatitis in individuals from endemic areas.⁶¹ *O. viverrini* and *O. sinensis* are considered carcinogenic to humans and have been included in the World Health Organization list as group I carcinogens.⁴⁹

FIG. 228.3 Adult worms of foodborne trematodes. This is a threefold magnification of selected adult flukes illustrating their relative sizes. Actual lengths: *Nanophyetus salmincola*, 0.8–2.5 mm; *Opisthorchis viverrini*, 5–10 mm; *Paragonimus westermani*, 7–16 mm; *Fasciola*, 20–30 mm; and *Fasciolopsis*, 20–75 mm. (From Mahanty S, MacLean JD, Cross JH. *Liver, Pathogens, and Practice*. 3rd ed. Philadelphia: Saunders; 2011:854-867.)

O. viverrini and *O. sinensis* are associated with cholangiocarcinoma in adults, and the former is presumed to be responsible for more than 60% of liver tumors in northeastern Thailand.⁴⁰

Diagnosis

Symptoms of acute infection may develop 3 to 4 weeks before eggs appear in the stool. Immunologic tests are useful to establish the diagnosis during this phase. Antibody-based tests are in use in some endemic areas but suffer from high rates of cross-reactions with antibodies to other parasites.^{53,64,103} The sensitivity and specificity vary depending on the antigens used. Enzyme-linked immunosorbent assay (ELISA) using excretory and secretory products performs better than crude antigen ELISA, but cost precludes widespread use.^{30,52} Demonstration of *O. viverrini* antigen in stool using a monoclonal antibody-based ELISA appeared to be specific and highly sensitive.^{53,97,103} A novel urine antigen test for the diagnosis of opisthorchiasis has proved to be more sensitive than stool egg concentration tests, but further evaluation of the test specificity is needed.¹¹⁷

In chronic infections, eggs are evident on fecal microscopy examination. The Kato Katz test is widely used but lacks sensitivity, especially in patients with very low parasite burdens. Concentration techniques such as the formalin-ether test are more sensitive than the Kato Katz test.^{8,41,43} Microscopy is useful in the clinical setting and in epidemiologic studies because it provides information regarding intensity of infection. Nonetheless, microscopic differentiation of *O. viverrini* and *O. sinensis* eggs is not easy. In addition, differentiation of these eggs from eggs of small heterophyid flukes is also difficult. Polymerase chain reaction (PCR)-based tests have shown promising results for the diagnosis of *O. viverrini* and *O. sinensis*.^{62,93} The loop-mediated isothermal amplification test, based on DNA polymerase with strand displacement at a constant temperature, may be even more sensitive.^{5,17,49,67}

Imaging studies may aid in the diagnosis of these flukes. Ultrasound findings include intrahepatic bile duct dilation, increased periductal echogenicity, and gallbladder sludge.^{28,76} Cholangiography often shows multiple cystic dilations of the ducts, elliptic or filamentous filling defects within the peripheral intrahepatic ducts, and intrahepatic duct haziness.²⁹ A combination of large cystic dilations and small cystic ectasias or mulberry-like dilations is considered diagnostic. The adult worms also may be visible on endoscopic retrograde cholangiopancreatography.

Treatment and Prognosis

All three *Opisthorchis* infections respond well to treatment with praziquantel.^{41,43,73,103} The recommended individual dose is 25 mg/kg given three times a day for 2 days. A single dose of 40 mg/kg also can be used, especially in control programs. At the recommended doses, praziquantel cures more than 80% of infected people.⁷³ Side effects of headache and dizziness are common occurrences. Treatment may decrease the risk for development of cholangiocarcinoma in those infected because regression of the bile duct lesions has been documented after praziquantel administration. Preliminary studies suggest that there may be efficacy for tribendimidine.¹⁰⁰ Two recent parallel dose-ranging phase II trials with tribendimidine for the treatment of *O. viverrini* showed that doses of 100 mg or higher were highly efficacious and safe among children (cure rate 98%) and adults (cure rate 77%) with light infections.⁹⁴

Prevention

The main barriers to prevention are deep-seated eating habits of raw or improperly cooked fish in endemic areas.¹¹⁸ Thus preventing contamination of fish ponds with human stool and decreasing the snail population in these settings helps decrease the prevalence of fish-borne fluke infections. An approach in which infected humans and other mammals are treated, sanitation is improved to avoid contamination of fishponds with raw human sewage, and health-promotion activities are carried out to decrease raw fish consumption is likely to have an impact on the incidence of infection.⁹⁸

Fascioliasis

Fascioliasis is a parasitic disease caused by the flukes *Fasciola hepatica* and *Fasciola gigantica*. With 91 million people at risk for acquiring infection, human fascioliasis is an important public health problem with an increasing incidence of human cases in 51 countries.^{16,41,42,75,81} Fascioliasis is primarily a zoonosis of ungulates (e.g., cattle and sheep). Although humans are considered an incidental host, the epidemiology of the disease is driven by human infection in hyperendemic areas.

Organisms

Fascioliasis is caused by two foodborne trematodes from the genus *Fasciola*, *F. hepatica* and *F. gigantica*. *F. hepatica* adult worms measure up to 30 mm in length and 13 mm in width. *F. gigantica* measures up to 75 mm.^{75,103} During chronic infection adult parasites reside in the bile ducts, where eggs are produced. They reach the intestine through the bile and are excreted in feces. Eggs measure 130 μ m in length and 90 μ m in width and are indistinguishable from those of *Fasciolopsis buski*, an intestinal fluke. After maturing in water for several days, the ciliated miracidium hatches and penetrates the freshwater snail host, where it undergoes a complex cycle of asexual multiplication. Cercariae leave the snail and encyst on freshwater vegetation, including watercress and alfalfa. These encysted metacercariae initiate infection when the mammalian host ingests the raw aquatic vegetation or water contaminated with metacercariae. The metacercariae excyst in the intestine, and the larvae penetrate the intestinal wall and migrate from the peritoneal cavity to the liver. The developing worms penetrate the liver capsule and slowly burrow through the parenchyma to the bile ducts, where they mature into the adult worms. Adult *Fasciola* attach to the bile ducts epithelium causing inflammation and ulceration, which facilitates feeding on the host blood.¹⁰⁵ The life span of the adult fluke in humans ranges from 9 to 13 years.

Transmission and Epidemiology

Epidemiologic studies suggest that human *Fasciola* infection is transmitted through ingestion of infected raw aquatic plants, such as watercress and

alfalfa, and by drinking untreated water with metacercariae.^{58,78,81} Herbivorous mammals, such as sheep, cattle, goats, and camelids, act as definitive hosts in nature. Fascioliasis has a worldwide distribution, with human infection reported from at least 51 countries in South America, the Caribbean, Africa, and Asia.⁸¹ The number of human cases is estimated between 2.6 million and 17 million, with more than half of the burden of infection reported from the Andean region and the Caribbean.⁴² More recent data suggest that those studies may have significantly underestimated the burden of disease. For example, reports from Bolivia and Peru showed a prevalence as high as 70% in some hyperendemic areas.¹⁶ The highest fascioliasis prevalence in the Andean region is observed in children, whereas in the rest of the world the infection prevalence is more evenly distributed among different age groups. Fascioliasis is emerging as a serious public health problem in Vietnam, with thousands of cases diagnosed in recent years.^{81,103,108} Similarly, outbreaks have occurred in Iran, with more than 17,000 clinical cases.^{47,91,92}

Pathology and Pathogenesis

Fascioliasis has an acute phase caused by juvenile flukes that migrate through the liver parenchyma and a chronic phase caused by the adult flukes that start egg production in the biliary tract. The pathogenesis of acute fascioliasis is related to direct liver damage caused by the migrating flukes and to the inflammatory reaction triggered by the fluke antigens. Linear necrotic lesions containing eosinophils form as flukes progress through the liver parenchyma. Flukes that die before reaching the bile ducts may produce necrotic cavities that eventually evolve into fibrous scar tissue. During the chronic stage, adult worms in the bile ducts cause inflammation and adenomatous changes in biliary epithelium, leading to duct thickening and dilation. Ductal and periductal fibrosis occurs. The gallbladder and extrahepatic ducts may be invaded and undergo similar inflammatory and fibrotic reactions. Adult worms may migrate back into the liver parenchyma through eroded biliary epithelium and cause formation of abscesses. Liver cirrhosis has been described in severe forms of fascioliasis. The inflammation associated with infection is probably associated with the anemia and weight loss that occurs with fascioliasis.

Clinical Manifestations

It is estimated that 15% of fascioliasis cases have high-intensity infections. As with other helminthes, those with a heavy burden of parasites are more likely to be symptomatic.⁴² Even those considered asymptomatic may suffer from anemia.⁷² Thus approximately 85% of *Fasciola* infections may remain subclinical and undiagnosed. Symptoms appear approximately 4 to 6 weeks after infection. The duration of this latent period depends on host response and the intensity of infection. The acute phase is characterized by right upper quadrant or generalized abdominal pain, tender hepatomegaly, fever, and anemia, typically associated with marked eosinophilia.^{6,12,43,56} Sweating, dizziness, wheezing, and urticaria may occur. This stage lasts 1 to 3 months. The chronic form of the disease is associated with symptoms of biliary system obstruction. These symptoms frequently are identical to those of gallbladder disease, cholangitis, and pancreatitis caused by nonparasitic conditions. Elevation in alkaline phosphatase levels is a common manifestation.^{6,12} Heavy and repeated infections eventually may cause liver damage sufficient to produce cirrhosis. Eosinophilia is not uncommon in chronic infections but is usually low grade. Juvenile flukes that fail to migrate into the liver may wander about and cause ectopic fascioliasis. The most common ectopic localization of immature *F. hepatica* flukes is in the subcutaneous tissues of the thorax, back, and extremities but also has been observed in lungs, heart, brain, and intestinal wall.¹⁰³ Blancas-Torres and colleagues reviewed a large series of fascioliasis patients (37 acute and 240 chronic) admitted to a hospital in Peru. A significant finding among these patients was the prevalence of weight loss (40%) and anemia (30%).¹² Severe acute disease may follow massive exposure and present with fever, eosinophilia, subcapsular hematoma, and tracks on imaging studies.⁷⁹

Diagnosis

The acute manifestations of human fascioliasis may precede the appearance of eggs in the stool by 7 to 12 weeks. The triad of fever, abdominal pain, and eosinophilia, combined with compatible exposures, helps to

suggest the diagnosis. Multiple immunodiagnostic tests are available to detect *Fasciola* during the acute phase of infection. Differences in sensitivity vary according to the antigens and antibodies used. The Fas2 ELISA test has a sensitivity of 92% and a specificity of 83%.³⁵ A commercially available sandwich ELISA using excretory-secretory antigens had a sensitivity and specificity of more than 95% when tested using serum of chronically infected individuals.¹¹² Serologic tests are also useful in the diagnosis of ectopic fascioliasis.

During chronic infection, *Fasciola* eggs may be detected in the stool. The Kato Katz and the rapid sedimentation tests are commonly used for microscopy diagnosis of fascioliasis, with the former being a quantitative test and the latter being significantly more sensitive.^{8,54} Because of the inconsistent egg production and intrinsic low sensitivity of microscopy testing, multiple stool specimens are often required. False-positive stool examination results may occur if the patient recently ingested raw infected liver containing *Fasciola* eggs. Serum and stool antigen tests are available for diagnosis in veterinary medicine, and studies in humans suggest that these tests are highly sensitive and specific, but no commercial versions for human use are available.^{16,31,111} PCR-based tests are at least as sensitive as coproantigen tests and may detect the infection as early.⁹⁰ In addition, they have the potential to differentiate *Fasciola* species. PCR targeting the ITS-2 region of the ribosomal DNA gene has shown the highest sensitivity and specificity. A loop-mediated isothermal amplification test has been used to successfully detect *Fasciola* DNA with 10⁴ times more sensitivity than conventional PCR in laboratory specimens.³ The loop-mediated isothermal amplification test could also differentiate *F. hepatica* from *F. gigantica*.³ However, no PCR-based test is available commercially for the diagnosis of fascioliasis in humans, and implementation of these in the traditional laboratory formats is unlikely in endemic areas.

Adult flukes may be seen on ultrasonography and appear as curvilinear lucent areas in the contrast medium in cholangiography. Endoscopic retrograde cholangiopancreatography may directly visualize the adult flukes, which are leaf shaped and bile stained. Eggs also may be identified in bile aspirates by microscopy. Radiologic imaging of the liver may demonstrate slowly evolving lesions, including track lines, small abscesses, and subcapsular hematomas.^{21,34,56,65,80}

Treatment and Prognosis

Unlike other trematode infections, fascioliasis is resistant to praziquantel. The drug of choice is triclabendazole at a dose of 10 mg/kg with a meal once or twice in 24 hours. The formulation manufactured for human use as Egaten is not approved by the US Food and Drug Administration and is only available through the Centers for Disease Control and Prevention under an investigational protocol in the United States. Triclabendazole (Fasinex) has been used for many years by veterinarians for treatment of livestock in endemic areas. Anecdotally, it has been used safely in humans. Triclabendazole has been used successfully in a variety of open clinical trials in adults and children for both acute and chronic fascioliasis.^{79,113} The drug is effective against both migrating flukes and established infections by adult parasites. However, resistance is a well-established problem in the livestock industry, with widespread resistance reported from several countries like Ireland, Australia, Spain, Argentina, and Peru.⁶⁰ Although not well studied and likely underreported, triclabendazole resistance is starting to emerge in human cases. Winkelhagen and colleagues¹¹⁵ reported a possible case of triclabendazole resistance in an elderly sheep farmer who failed several courses of treatment. Several cases of treatment failures to multiple ascending doses of triclabendazole have been reported in humans from Peru.¹⁵ Artemisinins have been used for the treatment of fascioliasis in two trials, with disappointing results.⁵⁹ Nonetheless, the combination of triclabendazole and artemisinins or ketoconazole showed promising results to overcome resistance in animal studies.⁸¹ Nitazoxanide may be used as an alternative to treat chronic fascioliasis, but reports about its effectiveness are inconclusive, and subjects with Triclabendazole-resistant infection did not respond to 7 days of treatment.^{15,36}

Prevention

Education and communication on safe growing of water plants for human consumption to avoid contamination with fecal material should

be promoted.^{81,103} Consumption of wild water plants in the field should be discouraged. Water purification systems should be implemented in highly endemic areas. The World Health Organization advocates the use of mass treatment with triclabendazole of children in endemic areas, but data are limited on safety and efficacy of this approach, especially in a setting of possible emerging resistance.^{113,118}

LUNG FLUKE

Paragonimiasis

The parasites of the genus *Paragonimus* are zoonotic parasites with felines, canines, and other carnivores as definitive hosts, snails as intermediate hosts, and crabs or crayfish as second intermediate hosts.^{10,41,58,75,103} More than 40 species of *Paragonimus* have been identified, at least 9 of which have been recovered from humans. The species causing human disease vary by region.

Organisms

The adult forms of *Paragonimus* form flattened leaf-like structures that measure about 7 to 16 mm long and 3.5 to 6 mm wide with anterior and ventral suckers.^{10,75} The adult worms typically are located in the lungs of the definitive host. The ova are large (80–120 $\mu\text{m} \times 48\text{--}65\text{ }\mu\text{m}$), yellow-brown in color, and contain a single operculum. Ova are shed into the bronchi and are either expectorated or swallowed and excreted in feces. After an incubation period of at least 2 weeks in fresh water, the free-living miracidia emerge and penetrate the snail intermediate host. After several weeks, the cercariae emerge and invade or are ingested by freshwater crabs and crayfish, forming cystic metacercaria in the tissues. Humans and other mammalian hosts are infected by ingestion of undercooked crab or crayfish. Larvae released from the metacercaria penetrate the wall of the intestines and migrate through the diaphragm to reach the lungs. In some instances, the worms may lodge in ectopic sites within the abdomen, liver, subcutaneous tissue, or central nervous system (CNS). The worms usually are found singly or in pairs within a capsule or cyst of reactive host tissue. Approximately 2 to 3 months are required from the time of ingestion until the worms are fully mature. Diploid forms reproduce sexually and triploid forms by parthenogenesis. In most infections, the worms die within 10 years; however, production of eggs for 20 years after the individual has left the endemic area has been reported.

In the past, most cases of paragonimiasis were attributed to infection with *P. westermani*, but molecular studies have revealed that more than nine different species of *Paragonimus* infect humans.^{10,11,50,75} Molecular characterization has shown that typical pleuropulmonary infections in China, Japan, and Korea were largely due to *P. westermani*.¹⁰ However, *P. skrjabini* and the related *P. skrjabini myazakii* cause atypical clinical disease in those areas.^{103,10,11} Although *P. westermani* is endemic in India and Southeast Asia, nearly all clinical isolates are *P. heterotremus*.^{32,33,96,122} Endemic areas with *P. africanus* and *P. uterobilateralis* can be found in Central Africa (Cameroon and Nigeria)^{4,85} and with *P. mexicanus* also the Pacific rim from Peru to Central America, with the major focus in Ecuador.^{10,51} Endemic cases have also been increasingly recognized in Missouri and are due to *P. kellicotti*.³⁷

Transmission and Epidemiology

The endemic areas for paragonimiasis are largely limited to areas where the ecology allows for infection of all of the hosts, including infection of freshwater snails, spread to freshwater crabs and crayfish, and ingestion of the crabs and crayfish by the definitive hosts.^{10,75} Human infection is acquired by eating freshwater crabs, crayfish, or shrimp that are raw, inadequately cooked, salted, or pickled. Recent cases acquired in the United States have been traced to ingestion of raw crayfish (*P. kellicotti*) or imported crabs (*P. westermani*).^{13,66} A number of autochthonous cases have been described associated with freshwater canoe trips in which raw crayfish were ingested on a dare.⁶⁶ Infection has also been associated with ingestion of undercooked wild boar meat, with the boar serving as a paratenic host. There are also reports of infection from ingestion of water contaminated with metacercaria from crabs.

The global prevalence of human infection is estimated at more than 20 million persons infected, with 293 million at risk.^{10,41,42} Overall, prevalence has been decreasing in much of east Asia such that disease is uncommon in Japan, Korea, Taiwan, Philippines, and eastern China, which once were highly endemic.^{10,42,69} However, recent studies demonstrate ongoing transmission in Kyushu Island Japan.⁸⁴ A study in the Zamboanga del Norte, Philippines noted a prevalence of 6.7% of subjects.⁷ Nevertheless, a recent national survey in China revealed a seroprevalence of paragonimiasis in 1.7%, with disease found in 21 different provinces.⁶⁹ Disease appears to be increasing in some areas after construction of the Three Gorges Dam.¹²⁵ Paragonimiasis remains endemic in much of Southeast Asia (including Vietnam, Thailand, and the Lao People's Democratic Republic). For example, seroprevalence ranged from 0% to 12.7% in parts of Vietnam,³³ and disease is described in all countries of southeast Asia as well as eastern India,^{32,96} where more than half of children were seropositive in one focus. *Paragonimus* is endemic in central and western Africa, but most human cases are reported from Cameroon and Nigeria, with up to 14.8% of the population seropositive in some regions of southwestern Cameroon.^{4,85} *P. mexicanus* is endemic in Latin America, with the primary focus in Ecuador and northern Peru, but case series have been reported from Colombia and Venezuela, in Central America, and as far north as Mexico.^{10,19,20,51}

Pathology and Pathogenesis

Larvae are released after ingestion of ova. The larvae penetrate the duodenum and enter the abdominal cavity aided by excretory proteases.¹⁰ Larvae may penetrate the diaphragm to the pleura soon thereafter, or the larvae may linger in the abdominal cavity or liver. After penetration of the pleura, the larvae burrow into the lung parenchyma and lodge near larger bronchioles or bronchi surrounded by an exudate of neutrophils and eosinophils. In time, this inflammatory response around the parasite organizes into a fibrotic wall that may measure up to several millimeters thick. The cysts usually are 1 to 2 cm in diameter and often are filled with a brownish material that likely contains hematin. Ova are released through communications with bronchioles or bronchi into sputum. Complications of paragonimiasis include bronchiectasis, fibrosis, interstitial pneumonia, and secondary bacterial infections.

Parasites can also be found in ectopic locations such as the CNS or subcutaneously. Ectopic parasites are more common for species that are less well adapted to the human host, especially *P. skrjabini*. Up to 31% of cases may involve the CNS in some areas.^{23,121} All areas of the brain and meninges are susceptible to invasion. The adult worms and the eggs cause areas of central necrosis and granuloma formation with dense collagenous walls surrounded by lymphocytes, plasma cells, eosinophils, and Charcot-Leyden crystals. The lesions vary in size and may be several centimeters in diameter and may appear cystic. Eventually, the wall may calcify. Spinal cord lesions are similar. The organisms can also cause a migratory subcutaneous nodule. Other sites at which worms may cause cysts or abscesses are the intestinal wall, mesentery, peritoneal cavity, liver, diaphragm, and myocardium.

Clinical Manifestations

Classical (pleuropulmonary) paragonimiasis. The classical presentation of paragonimiasis is with pleural or pulmonary disease.^{41,43,75} Pulmonary disease is more common with species better adapted to the human host (e.g., *P. westermani*, *P. heterotremus*, or *P. africanus*)^{32,33,69,85} than species less adapted to the human host (e.g., *P. skrjabini*).¹⁰ Migration of the worms from the intestinal tract to the lungs does not usually cause symptoms but has rarely been associated with fever, abdominal pain, diarrhea, and eosinophilia. However, if the parasites migrate across the liver, patients frequently present with abdominal pain and eosinophilia.⁶⁸ As the parasites enter the pleura, patients may present with fever, chest pain, dyspnea, cough, malaise, and night sweats. The pulmonary clinical manifestations are mainly a chronic cough. Cough may be dry or associated with sputum production, which may be described as mucoid, rust colored, or blood streaked. Hemoptysis usually is intermittent and occasionally may be severe. Eosinophilia is a common finding in the

early stages of infection but may return to normal over a period of months or years. Complications may include pneumothorax, pleural effusion, empyema, and pneumonia. The presence of hemoptysis and cavitory lung lesions can be confused with tuberculosis, but tuberculosis typically has more systemic symptoms (e.g., fevers, night sweats, and weight loss). However, systemic symptoms have been noted in most recent cases from North America.⁶⁶

Nonclassical presentations. Paragonimiasis may also infect other sites, including the subcutaneous tissues, brain, liver, abdomen, pericardium, and abdominal cavities. Extrathoracic disease is more common with parasites less adapted to the human host, especially *P. skrjabini*, but has been described from all endemic areas.¹²⁵

Up to 31% of cases may involve the CNS.²⁶ Cerebral involvement is more common in children than adults.¹²¹ Most cases present with headache, nausea, and vomiting. Others may present with focal findings (e.g., aphasia, motor involvement, or sensory abnormalities). Patients also may have seizures, which are usually described as generalized. They may or may not have coexisting pleuropulmonary disease. Spinal cord lesions often are extradural and mimic mass lesions caused by tumors or infection.

Cutaneous paragonimiasis presents with subcutaneous nodules, which may be fixed or slowly migrate. Cutaneous nodules can account for up to 42% of cases in areas endemic for *P. skrjabini* but are also noted in other areas. Worms recovered from these lesions are immature.

Diagnosis

Most patients have pleuropulmonary symptoms, and initial evaluation includes a chest radiograph. Radiographs initially may be normal but more typically demonstrate pleural effusions, nodules, or infiltrates.^{32,48,55,63,85} Other radiographic findings include cavitations and fibrosis. Nodules and cysts can be found in any part of the lungs, but tend to localize in the periphery of the middle and lower lung fields. A common radiographic diagnostic feature is a “ring shadow.” This finding represents the circular or oval thin-walled cyst with a crescent-shaped opacity along one side. Chest computed tomography (CT) findings vary by region (and thus likely by parasite species). Studies from Korea noted infiltrates and nodules in most cases.⁶³ Studies from Laos and India were more likely to show multiple cavitory lesions.^{32,55} North American series noted more pleural effusions, pericardial involvement, and lymph nodes.⁴⁸

Cerebral paragonimiasis may be seen as either an avascular mass or a hemorrhage on CT or magnetic resonance imaging.^{1,23,26,120} Findings may include low-density, irregular shadows in most cases or, less frequently, hemorrhages. Either can be associated with edema and contrast enhancement. The ring enhancement may involve clusters of rings. In long-standing cerebral infections, the cystlike structures may calcify and be seen as a cluster of “soap bubbles.” The individual oval or spherical bubbles may measure 2 to 40 mm in diameter, and a cluster of these structures may extend 10 cm.

Nearly all cases of paragonimiasis will present with eosinophilia. There can be some variability such that some authorities recommend repeating blood counts if eosinophilia is not present on the initial examination. Radiologic studies play a key role in diagnosis.

Pulmonary paragonimiasis is diagnosed definitively by finding the characteristic eggs in sputum or stool from a patient with symptoms suggesting the infection. Ova are more readily visualized with concentration or Ziehl-Neelsen staining.⁹⁹ Eggs are not present until 2 to 3 months after infection develops. Concentration techniques may help identify eggs in patients with light infections. Eggs have also been identified by percutaneous aspiration of lung nodules.¹²⁴ Several immunodiagnostic tests, including ELISA and immunoblotting, have been developed, which may assist with confirming the presence of infections. Immunodiagnosis is especially useful in infections in which eggs are not demonstrated easily, such as in cerebral paragonimiasis. The immunoblot assay performed with a crude antigen extract of *P. westermani* has a sensitivity of 96% and specificity of 99% and is the serodiagnostic test of choice.⁸⁶ Tests that amplify parasite DNA, including loop-mediated amplification, may improve sensitivity but are not widely available.²⁵

Treatment and Prognosis

Praziquantel 75 mg/kg divided into three doses is given daily for 2 or 3 days.^{41,43} Triclabendazole has been studied as an alternative treatment for humans infected with *Paragonimus* spp.¹⁸ One study demonstrated 84% to 90% efficacy with single-day regimens of one or two doses of triclabendazole for the treatment of pulmonary paragonimiasis.^{18,41}

The prognosis is good in most pulmonary infections, even if they go untreated, although symptoms may persist for many years. Treatment effectively resolves the pulmonary lesions and symptoms. The prognosis for CNS involvement depends on the location and extent of the lesions but is usually grave.

Prevention

The key in prevention is education of the population in endemic areas concerning the source of infection. Crabs and crayfish, prepared in a manner that transmits paragonimiasis, are delicacies in many parts of the world. However, education about preparation of these foods has led to dramatic reductions in the number of cases in Japan, Korea, the Philippines, and eastern China. Mass chemotherapy is being used to try to help prevent infections. Because paragonimiasis is a zoonosis, however, it is less amenable to control by mass treatment of human populations or improved sanitation.¹¹⁸

INTESTINAL FLUKES

Approximately 40 to 50 million people are thought to be infected by one or more of the 70 species and 14 families of intestinal flukes.^{22,58,75} They are diverse morphologically, ranging in size from the *F. buski* (7.5 cm in length) to the tiny heterophyids (1–2.5 mm in length). Most cases cause few symptoms. However, heavy infections have been associated with a number of gastrointestinal symptoms. The most widely recognized organisms include *F. buski*, *Heterophyes* spp., *Metagonimus yokogawai*, and *Echinostoma* spp.

Fasciolopsiasis

Life Cycle

Fasciolopsiasis is a foodborne intestinal zoonosis caused by *F. buski*, the giant intestinal fluke.^{22,44,45,75,103} The adult fluke measures up to 7.5 cm in length and attaches to the duodenum and jejunum walls. The life span of adult *Fasciolopsis* is approximately 6 months. Egg production starts about 3 months after infection, and these are 130 to 150 µm in length by 80 to 85 µm in breadth. A single parasite may excrete 25,000 eggs daily. The eggs are released in the feces, and after several weeks in fresh water, ciliated larvae hatch from the eggs and penetrate snails, where they reproduce asexually undergoing several larval stages. Cercariae emerge from the snail approximately 1 to 2 months later and encyst as metacercariae on a wide variety of aquatic vegetation and debris as well as on the water surface. Mammalian hosts are infected after ingestion of the metacercariae. Pigs are common reservoir hosts. Water chestnuts, caltrop, and water bamboo are common sources of human infection. Ingestion of larvae also can occur through drinking untreated water or handling water-derived plants (e.g., peeling contaminated water chestnuts with the teeth).

Epidemiology

Fasciolopsiasis occurs most often in Asia and the Indian subcontinent, with high prevalence rates recorded in parts of south Asia and Thailand.^{2,22,44,45,103,116} Pigs are the definitive host, and the prevalence of fasciolopsiasis is higher in areas where pigs are raised and aquatic plants are consumed. Fasciolopsiasis is most prevalent in school-aged children, in whom high worm burdens are not uncommon findings.

Pathology

The parasites infect the duodenum and jejunum, but in heavy infections they can be observed in the stomach, ileum, and colon. Inflammation, ulceration, and small abscesses sometimes develop in the intestinal mucosa where the parasite is attached. Increased mucus secretion and mild bleeding can result. Light infections typically are asymptomatic. Massive infections can lead to intestinal obstruction and perforation.

Complications such as malabsorption and protein-losing enteropathy are common occurrences in heavy infections and can lead to generalized edema and ascites.

Clinical Manifestations

The severity of symptoms is correlated with the burden of parasites. Epigastric discomfort has been reported as early as 30 days after exposure. Diarrhea and abdominal pain may be intermittent and may occur separately. Patients may note passing fleshy masses in stool.² In heavy infections, nausea and vomiting may develop. Facial edema, anasarca, ileus, and intestinal perforation are encountered in severe infections. Eosinophilia with counts greater than 30% is not an uncommon occurrence. Leukocytosis and mild anemia may be noted.

In endemic areas, fasciolopsiasis contributes to malnutrition in children, especially when associated with other helminth infections. Fasciolopsiasis adds an additional burden to the host and in concert with other chronic helminth infections may be responsible for significant morbidity.

Diagnosis

The eggs of *Fasciolopsis* are demonstrated easily by routine fecal examination, but they are virtually indistinguishable from those of the liver fluke *F. hepatica* and the echinostomes. Epidemiologic information, such as travel history and exposure to sources of infection, may be helpful in determining the diagnosis. Because the life span of adult *Fasciolopsis* is short, anyone who has been out of an endemic area for longer than 9 months is not likely to have fasciolopsiasis. Incidentally, fasciolopsiasis can be diagnosed by upper endoscopy.

Treatment and Prognosis

Praziquantel 75 mg/kg divided into three doses given in 1 day is effective and safe. Infections treated early and most light infections, even when they are untreated, have an excellent prognosis. Heavy infections in children, especially when they are complicated by intestinal obstruction, edema, or concomitant secondary infections, portend a much poorer prognosis.

Prevention

Avoiding raw water plants and untreated water may be a practical approach to prevent fasciolopsiasis. Cooking aquatic vegetation or immersing the plants or nuts briefly in boiling water usually is sufficient to prevent infection. Also, discouraging the use of human feces as fertilizer and promoting the institution of modern pig farming both can aid in the control of fasciolopsiasis. Successful efforts in health education or mass chemotherapy have reduced the transmission of this parasite in some endemic areas^{103,114}; however, in areas where fasciolopsiasis was presumed controlled, such as Uttar Pradesh, reemerging infection has been reported.⁹

Heterophyiasis

More than 11 different species of the family Heterophyidae have been reported to cause human infection.²² *Heterophyes* spp., *Haplorchis* spp., and *M. yokogawai* are common human parasites, whereas other organisms are uncommon.

Organism

Heterophyes spp., *Haplorchis* spp., and *M. yokogawai* adult worms attach to the mucosa of the small intestine. The parasites are minute, measuring 1 to 2.5 mm in length and less than 1 mm in width. They often burrow deeply into the mucosa. The eggs measure 26 to 30 µm in length and 15 to 17 µm in width. The eggs are nearly identical. Eggs excreted in the stool are fully embryonated. The snail intermediate host becomes infected by ingesting the trematode egg. After multiplication in the snail, cercariae emerge and encyst as metacercariae under the scales or skin or in the muscle of a variety of freshwater fish. After being ingested by the definitive host, the metacercariae are freed from their cysts and develop into adults in as little as 5 days.

Transmission and Epidemiology

Humans acquire the infection by eating freshwater fish that is raw or inadequately cooked. Transmission may have a seasonal pattern, with

the highest fish infection rates found during the summer.^{24,70,110} Heterophyiasis occurs worldwide. Areas of endemic infection are Southeast Asia, the Middle East, the Nile Delta, China, Japan, Taiwan, the Philippines, and parts of the former Soviet Union. Many reservoir hosts, such as dogs, cats, and fish-eating birds, may play an important role in maintenance of infection in some endemic areas.

Pathology

The small heterophyid flukes cause variable degrees of inflammation in the intestinal wall.²² Superficial inflammation and erosions are found at the sites of mucosal attachment. Eggs deposited beneath the mucosa cause eosinophilic granulomatous lesions. Eggs may invade the circulatory system through the intestinal capillaries or lymphatics. Eggs may reach distant sites such as the heart, brain, and spinal cord, causing significant morbidity and even mortality. The embolized eggs induce a granulomatous response, with the eventual production of fibrosis in the infected areas. The complications of embolic heterophyiasis appear to be particularly frequent in the Philippines, where heart disease often is attributed to heterophyiasis.

Clinical Manifestations

Light infections without the deposition of ectopic eggs usually are asymptomatic, although eosinophilia may be noted. In heavier infections, epigastric pain, diarrhea, malabsorption, and weight loss may occur. Seizures may result from eggs carried to the brain. Congestive heart failure or arrhythmias may occur after cardiac involvement.

Diagnosis

Routine fecal microscopy may demonstrate eggs. Nonetheless, differentiating morphologically heterophyid eggs from those of the liver flukes may be difficult. Eggs recovered from patients who have been exposed more than 2 years before presentation are very likely to be from *Opisthorchis* or *Clonorchis* because the life span of heterophyids is usually less than a year.

Treatment and Prognosis

Praziquantel 75 mg/kg per day in three divided doses for 1 day is the recommended treatment. With the exception of the complication of egg emboli to distant organs, the prognosis is excellent.

Metorchiasis

M. conjunctus, endemic in North America; *M. bilis*, in Russia; and *M. orientalis*, in China and Korea, are members of the Opisthorchiidae family. They have a life cycle similar to that of the other opisthorchids. A wide variety of fish-eating mammals may serve as definitive hosts. This infection is a significant cause of morbidity and mortality in sled dogs in Canada. It is an occasional incidental finding on fecal examination in native communities in northern Canada. An outbreak of 19 cases of *Metorchis* infection was related to fish prepared raw as sashimi.⁷⁴ The epidemiology of metorchiasis outside North America seems to be far from an incidental illness. In areas where the epidemiology of *O. felinus* and *M. bilis* overlap, the difficulties differentiating *M. bilis* from *O. felinus* eggs have led to overdiagnosis of opisthorchiasis and the impression that it is much more common than metorchiasis.⁸³ National surveys in China have identified some foci of human *M. orientalis* infection in the Fujian province. The severity and duration of the symptoms probably correlate with parasite burden. The symptoms during acute infection are fatigue, upper abdominal tenderness, fever, epigastric abdominal pain, headache, weight loss, anorexia, nausea, diarrhea, vomiting, muscle pain, backache, cough, and rash.⁷⁴ The degree of eosinophilia and elevation in liver enzymes are proportional to the intensity of infection. Eggs are noted in stool 10 days after infection develops. Praziquantel is effective during acute metorchiasis and in the chronic phase.

Schistosomiasis

229

Philip R. Fischer • A. Clinton White Jr

Approximately 260 million individuals are infected with parasites of the genus *Schistosoma*,^{38,88,157,167,210} and another 700 million people are at risk for infection.^{175,210,209} Many are unaware of their infection, although approximately 20 million people have severe disease with potentially fatal portal hypertension, urinary tract involvement, renal failure, and bladder cancer. Initial infection usually occurs during childhood. The prevalence typically peaks in the teen years, and, although most of the morbidity occurs in adults, symptomatic disease develops in millions of children.

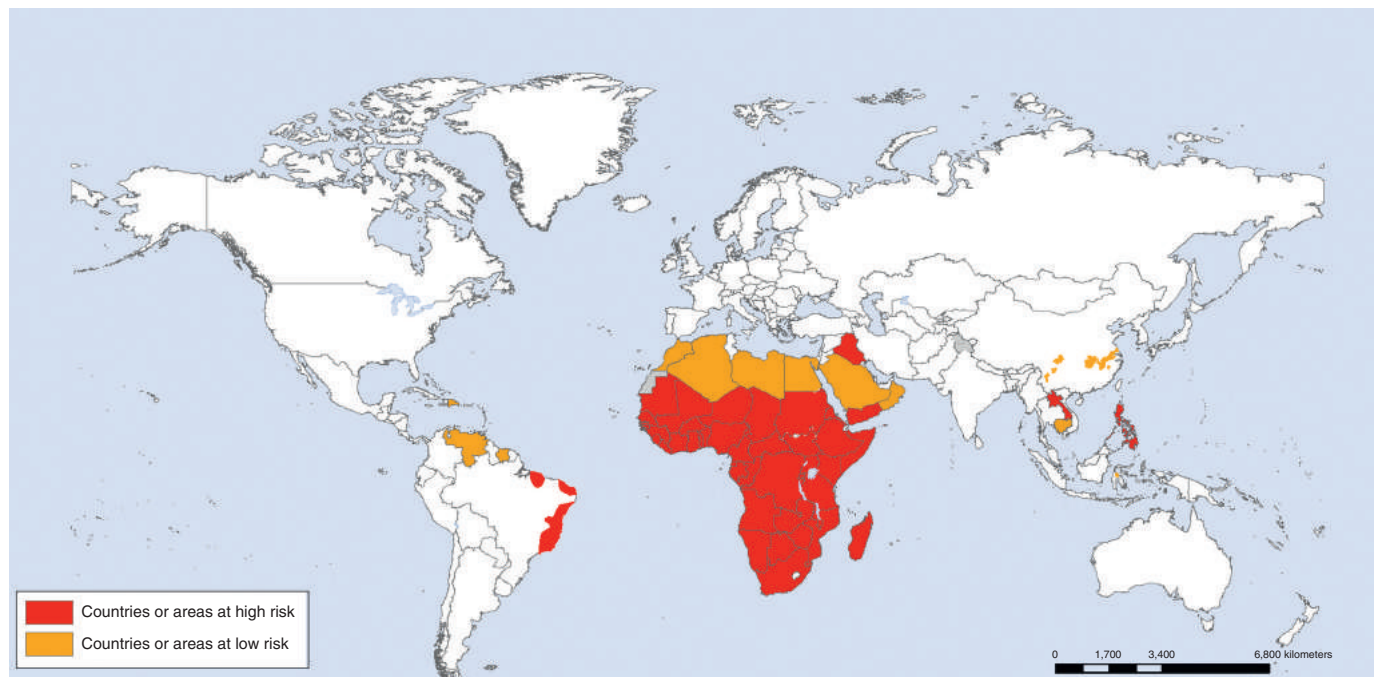

There is historical evidence of schistosomiasis occurring as early as the second millennium BCE.^{186,188} For example, *Schistosoma* eggs have been found in mummies from the 20th dynasty in ancient Egypt and in ancient China. In 1851, Theodor Bilharz identified the parasitic etiology of endemic hematuria. At the same time, the association between *Schistosoma* and Katayama fever was recognized in Japan. The complete life cycle was identified during the first decades of the 20th century. Before the development of effective curative medication in the 1970s, schistosomiasis was considered the “most dreadful of the remaining plagues of Egypt.”^{88,89} Nonetheless, it had been reported in 1919 that “it is now quite within the bounds of possibility that the disease may be largely controlled”¹⁵⁶; even in this new millennium, success with disease control and eradication is still quite limited. Of 259 million people requiring treatment for schistosomiasis in 2014 (of whom 48% were school-aged children), only 62 million individuals actually received treatment.¹⁶⁷

EPIDEMIOLOGY

Schistosomiasis is caused by helminth parasites of the class Trematoda, which includes the flukes. Schistosomes differ from other human flukes

in that they live within the vascular system and have separate male and female sexes. Humans are the definitive host for six species within the *Schistosoma* genus.^{186,188} *Schistosoma haematobium* is the cause of urinary schistosomiasis. *Schistosoma japonicum* and *Schistosoma mansoni* are common causes of disease resulting from infection of the intestinal vasculature. *Schistosoma mekongi* (in Asia), *Schistosoma guineensis* (in West Africa), and *Schistosoma intercalatum* (in Central Africa) also cause infection along the intestinal tract but are found only in small geographic areas.⁴⁰ Other mammalian *Schistosoma* species occasionally infect humans.

Each species of *Schistosoma* uses fresh-water snails as obligate intermediate hosts,^{186,188} and the geographic distribution of *Schistosoma* is limited by the habitat of these snails (Fig. 229.1). Oncomelania snails transmitting *S. japonicum* live in the moist soil along slow-flowing streams and irrigation canals, limited primarily to parts of China, the Philippines, and Indonesia. The *Bulinus* snails associated with *S. haematobium* and the *Biomphalaria* snails associated with *S. mansoni* live in shaded, slow-flowing, shallow water. *S. haematobium* is seen primarily in tropical Africa, along the Nile River, and in the Middle East. In addition, however, *S. haematobium* has recently been identified in Corsica, France.¹⁸ *S. mansoni* is found across tropical Africa, along the Atlantic coast of South America, and on some Caribbean islands. *Tricula*, the snail host for *S. mekongi*, is limited to the Mekong River in Laos and Cambodia. *S. intercalatum* and its snail host *Bulinus* spp. are found only in Cameroon and the Democratic Republic of Congo. Most human infections occur when children come into contact with fresh-water streams, rivers, or lakes inhabited by infected snails (Fig. 229.2).¹⁸⁸ Thus transmission typically occurs during routine activities such as obtaining water for household use, bathing, fishing, and irrigation. Humans are infected by the fork-tailed schistosomal cercariae. Cercariae penetrate the skin with the aid of secretory serine proteases.^{114,166} During

penetration, the parasites lose their tails and modify their tegument to form the schistosomula stage. Schistosomulae enter the bloodstream and then migrate to the lungs. They move from the pulmonary arterial circulation to the venous circulation without exiting the vessels. The parasites then travel through the systemic circulation until they reach splanchnic vessels and gain access to the portal system.

During the course of a few weeks, the schistosomulae develop into mature male and female adults that mate continuously.^{187,188} Adult worms are 1 to 3 cm in length and usually live for 3 to 7 years. *S. haematobium* localizes to the venules of the urinary bladder, *S. japonicum* goes to the superior mesenteric vessels, and *S. mansoni* goes to the inferior mesenteric vessels. The gravid females migrate upstream to lay eggs near the bladder or intestines. Each adult female can produce hundreds (in the case of African species) to thousands (for Asian species) of eggs per day.⁷⁵ Most of the eggs become embedded in the walls of the peripheral vessel where they were laid. However, some of them flow with the blood and can stimulate reactions and cause disease at other sites. A localized granulomatous response allows the eggs to pass through the wall of the bladder (for *S. haematobium*) or the intestine (for other species) to be released in urine or stool. Released eggs mature in a week's time and then hatch to release miracidia. The miracidia penetrate the snail to continue their life cycle and eventually develop into hundreds of cercariae.

Infection is seen in children as young as 6 months; exposure to cercariae often is greatest in boys between the ages of 5 and 10 years.^{88,96,186} In lakeside Ugandan villages, however, nearly half of the children are infected during the first 3 years of life,¹⁴⁰ and in a western Kenya town, infection was noted in 14% of 1-year-olds, 63% of 5-year-olds, and 90% of 10-year-olds.²⁰¹ The peak intensity of infection, as measured by excretion of eggs, occurs in children 8 to 12 years old in heavily infected areas and takes place during the teenage years in more lightly infected areas. The intensity and the incidence of excretion of eggs decline after the adolescent years, and hormonal changes during puberty are associated with increased resistance to infection.¹⁰¹

PATHOGENESIS AND IMMUNITY

Within hours of penetration of the skin, local erythema and inflammation may result from the activity of parasite proteases.^{113,165,192} In individuals previously sensitized, a delayed immune reaction may cause papular or vesicular lesions.^{97,186} Infiltration of the epidermis and dermis with a mixture of mononuclear cells and eosinophils causes papules. This reaction (termed swimmer's itch) is more pronounced for avian schistosomes, which are unable to penetrate into the human circulation and die in situ. During the initial migration of schistosomes through the lungs, patients may develop fever, pneumonitis, pulmonary infiltrates, and eosinophilia. However, these reactions resolve spontaneously.

Acute schistosomiasis typically begins 2 to 12 weeks after exposure, at the time the female parasites begin to produce eggs.^{53,159} This condition was initially recognized with *S. japonicum* but is now described with all species.^{97,106,118,186} Patients characteristically have marked eosinophilia, along with immunoglobulin E (IgE) and IgG antibodies to the parasites, consistent with an active helper T-cell subtype 2 (Th2) response.^{97,186} However, studies suggest that proinflammatory cytokines play an important role.^{50,133} The antibodies react with egg antigens, which cross-react with antigens from the cercaria or schistosomula stages.^{10,82,83} During early production of eggs, the quantity of antigen exceeds that of antibody, and soluble immune complexes are formed. Immune activation and immune complex deposition lead to the clinical manifestations, including fever, myalgia, urticarial rash, and bloody diarrhea. Pulmonary nodules and infiltrates may be noted during acute infection.^{43,168} In addition, acute infection can be complicated by ectopic egg production. Patients with acute *S. mansoni* or *S. haematobium* infection occasionally can have neurologic involvement.^{32,60,149} Interestingly, acute disease occurs rarely in endemic populations, perhaps because of modulation of the immune response from exposure to parasite antigens in utero.

Chronic Schistosomiasis

Despite the fact that the adult worms live within the bloodstream, they cause little host response. The parasite surface incorporates blood group

glycoproteins and major histocompatibility antigens and downregulates expression of its own surface proteins, which may help the adults evade immune system attack.^{72,146,177}

Chronic infection is characterized by localized granulomas surrounding the parasite eggs.^{97,157,186} Excretory products of the eggs (termed soluble egg antigens) are the major antigens. The egg antigens are cytotoxic to host cells, such that infection of mice lacking T cells results in increased localized necrosis surrounding the eggs; the granulomas help protect the host from the ravages of the eggs. Interleukin-17 (IL-17) mediates the formation of granulomas in the liver.²¹⁸ The granulomas also facilitate transit of the eggs into stool and urine, as illustrated by the fact that immunodeficient hosts tend to have lower rates of shedding of eggs despite having high concentrations of eggs in tissues.^{52,92,135} High levels of vasoactive endothelial growth factor and angiogenesis are associated with initial granuloma formation.¹⁷³

The granulomas also contribute to the pathologic process. They are composed of a mixture of eosinophils, lymphocytes, macrophages, and granulocytes.²⁰ Late-stage granulomas also contain fibroblasts, collagen, and giant cells. Initially, antigen-presenting cells stimulate CD4⁺ T cells to produce IL-2, tumor necrosis factor- α (TNF- α), and interferon- γ (IFN- γ).¹³⁴ Early expression of TNF- α plays a key role in the initial formation of granulomas.⁵ A subsequent shift occurs toward production of Th2 cytokines (e.g., IL-4, IL-5, IL-10, and IL-13) along with antibody.¹⁴⁷ This event is accompanied by eosinophil recruitment. IL-4 and IL-13 also play a primary role in the development of hepatic granulomas, and IL-13 expression is linked closely to the development of fibrosis in murine models.^{36,37,41} Subsequent immunomodulation, largely mediated by IL-10 and transforming growth factor- β (TGF- β), results in downsizing of the granuloma and suppression of the inflammation.^{9,57,63,84,121,133,174,204} However, depletion of IL-4 results in tissue damage.⁴¹ When granulomas are limited to the intestines, the cytokine response is dominated by antiinflammatory cytokines (e.g., IL-10 and TGF- β), and patients have few symptoms.⁴⁵ By contrast, patients with granulomas in the liver are more likely to be symptomatic. They express more inflammatory cytokines, including IL-13 and TNF- α . TGF- β also is associated with fibrosis in primate models,⁵⁷ whereas Th1 cytokines (e.g., IFN- γ and IL-12) suppress fibrosis.^{22,211,219} Macrophages activated by IL-4 and IL-13 (alternative rather than classical IFN- γ -based activation) seem to protect mice against schistosomiasis-induced inflammation and fibrosis with the acute infection while later promoting fibrosis with chronic infection.¹³ Eosinophils modulate peripheral blood mononuclear responses to adult worm antigens.¹⁹⁶

IL-13 in particular stimulates the formation of fibrosis in the portal tracts,³⁶ probably through the induction of expression of fibrosis-associated genes.¹¹⁷ Portal fibrosis, in turn, leads to the development of portal hypertension (i.e., hepatosplenomegaly, ascites, and esophageal varices).⁹⁷ Death from hepatic schistosomiasis typically results from gastrointestinal bleeding. Overt bleeding is an uncommon occurrence in children, but it can occur in adolescents and young adults. In patients with isolated schistosomiasis, hepatocellular function is surprisingly normal.²⁰ Patients are thought to tolerate even gastrointestinal bleeding better than do those with cirrhosis. By contrast, progressive hepatocellular damage and rapid progression to liver failure develop in patients coinfecting with hepatitis viruses, particularly hepatitis C.^{7,42,91} The immunomodulation that develops in response to schistosomiasis is thought to suppress immune control of the hepatitis virus. Whether schistosomiasis-associated immune changes alter susceptibility to or expression of human immunodeficiency virus is unknown.²⁰⁰

Reinfection after treatment is more common in children younger than 10 years and with higher IgG4 levels.¹²⁸ In some settings, boys are more likely to be reinfecting than girls,¹²⁵ but this is not uniformly true.¹²⁸ Higher IgE levels are associated with less reinfection.¹²⁸

Interestingly, patients with schistosomiasis are less susceptible to allergies.^{28,139,199} Evidence indicates that asthmatic patients with schistosomiasis produce lower levels of IL-5 and greater levels of IL-10 than do asthmatic patients without schistosomiasis, and it is this suppression of Th2 responses that might modulate the expression of asthma and atopic disease in patients with schistosomiasis.⁸ Alternatively, it is possible that a common genetic predisposition alters the risk for subsequent development of both atopic disease and schistosomiasis.^{12,120} A

population-based study in Zimbabwe identified a negative correlation between atopy and the intensity of schistosomal infection in a village with a high frequency of schistosomiasis but not in a village with lower infection frequency,¹⁶² indicating the interrelatedness of schistosomal antigenic stimulation and the development of allergic disease.

Several means exist by which schistosomiasis might be related to anemia, and the exact pathologic mechanisms are not fully understood.⁶⁶ At least sometimes, however, the anemia is due to inflammation rather than iron deficiency.^{104,126} Generalized undernutrition is associated with schistosomiasis; proinflammatory cytokines (IL-1 β) and generalized inflammation (as manifested by elevated levels of C-reactive protein) are contributing factors.⁴⁷ Even without acute inflammation, schistosomal infection and periportal fibrosis are associated with reduced vitamin A status and high oxidative stress (increased serum hydroperoxides).¹⁷ Schistosomiasis-affected children have lower levels of regulatory T cells with altered cytokine responses; this seems to provide some protection against concurrent malaria infection.¹¹⁹ Similarly, parasite-induced changes in the Th1/Th2 balance are hypothesized to explain how young children with underlying schistosomiasis are less likely to develop malaria.¹²⁰

Approximately 40,000,000 women of childbearing age are infected with schistosomes. Although mechanisms are not clear, some evidence indicates that schistosomiasis during pregnancy is associated with decreased birth weight and a higher risk for preterm delivery.⁶⁷

Urinary Schistosomiasis

Genital and urinary schistosomiasis also is the result of granuloma formation. Severity of disease correlates with increased production of TNF- α and decreased production of IL-10.³⁹ Direct inflammatory responses to eggs along the ureters or from obstruction to ureteral drainage caused by space-occupying granulomas in the bladder wall block ureteral emptying.^{95,178} All tissue layers may be involved, but pathologic changes are usually most extensive in the submucosal layer.⁹⁴ Abnormal ureteral flow, dilatation, and hydronephrosis develop.¹⁷⁸ In some communities where *S. haematobium* is common, ureteral deformities demonstrable on intravenous pyelography are noted in half of affected children and hydronephrosis develops in more than 10%.⁹⁸ Eventually, scarring and calcifications form and may be associated with chronic hydronephrosis, even with resolved or light chronic infection.^{99,178} The hydronephrosis and urinary stasis predispose patients to chronic bacteriuria and urinary tract infections.

In *S. mansoni* infection, immune complexes may mediate glomerulonephritis, as evidenced by the finding of schistosome-derived immune complex deposits in glomeruli.^{15,180} Nephrotic syndrome has been reported in association with chronic schistosomiasis.^{123,124} Amyloid deposits have been found in the kidneys of children with chronic schistosomiasis, and this condition probably is caused by immune responses that are altered by the chronic parasitic infection.^{14,202}

Squamous cell carcinoma of the bladder is a common occurrence in areas of heavy infection with *S. haematobium*, but otherwise it is a rare form of bladder cancer.^{99,178,186} The prolonged irritation of bladder epithelium by schistosome eggs and the resulting immune response are thought to trigger hyperplasia and subsequent malignant disease.¹⁰⁵ In an animal model, direct exposure to schistosomal antigens stimulates increased proliferation and decreased apoptosis of endothelial cells along with downregulation of tumor suppressor p27 and upregulation of antiapoptotic molecule Bcl-2.²⁴ This condition could be aggravated by urinary stasis in the bladder with secondary increases in pH that favor malignant transformation of epithelial cells. Carcinogenic tryptophan metabolites also have been postulated to link the nutritional activities of parasites near the bladder with subsequent carcinogenesis. Schistosoma-related bladder cancers have biomarker prevalence different from that of nonschistosomal bladder cancers, and this might influence eventual treatment choices.²

CLINICAL MANIFESTATIONS

The main clinical manifestations of schistosomiasis vary with the stage of the parasite's life cycle and also differ among species. Many patients remain asymptomatic. Patients with asymptomatic schistosomiasis may

be identified during community screening programs in an endemic area, through immigrant or returned traveler evaluations in a nonendemic area, or when diagnostic tests such as urine or stool microscopy are performed to evaluate other, seemingly unrelated symptoms. The minority of infected children, those with heavy infections, are most likely to develop early symptoms and also are at greatest risk for subsequent major health complications.

Cercarial Penetration

Within a few minutes of coming into contact with cercariae, some children develop pruritus. This response to initial contact with the parasite occurs more commonly in nonimmune visitors to endemic areas than it does in indigenous residents of endemic areas, but it seems to be more pronounced after repeated exposure to cercariae than on the first exposure. It may occur after contact with any of the human *Schistosoma* spp. but more commonly results after contact with the cercariae of avian schistosomes. An erythematous and sometimes papular rash may develop.^{97,186} The rash usually subsides during a period of 2 to 10 days without scarring, regardless of whether specific treatment is given.

Acute Schistosomiasis (Katayama Fever)

Acute schistosomiasis, referred to as Katayama fever, typically begins 2 to 12 weeks after exposure, when the adult worms begin to produce eggs.^{52,87,159} Clinical manifestations of acute schistosomiasis usually include high fever, chills, myalgia, headache, and a general ill appearance.^{50,53} An urticarial rash, which may include giant urticaria, and diffuse lymphadenopathy may be seen.^{154,221} Cough, rales, and pulmonary infiltrates may be noted, even in the absence of fever.^{43,168} Gastrointestinal symptoms of anorexia, abdominal pain, and loose stools sometimes are observed. Bloody diarrhea may be seen acutely with heavy infections by *S. japonicum* and *S. mansoni*. Tender hepatomegaly and mild splenic enlargement develop in approximately 30% of children with Katayama fever. Some reports suggest that myelopathies are a common accompaniment of acute schistosomiasis.^{60,149} Genital symptoms (primarily hematospermia) also are frequent initial symptoms.^{44,153} Marked eosinophilia often is seen with acute schistosomiasis.

Urinary Schistosomiasis

Hematuria is the classical finding of *S. haematobium* infection.^{26,51,95,186,207} In some highly endemic areas, for boys nearing puberty not to display this evidence of "male menstruation" is considered abnormal. Typically, hematuria results from the release of blood from irritated, inflamed areas around granulomas in the bladder wall as the bladder contracts during micturition.¹⁷⁸ Thus the blood is most obvious at the end of the urine stream ("terminal hematuria"). The hematuria usually is not associated with pain or discomfort, but dysuria can be present.^{1,26} With chronic infection in children who either were not treated initially or were reinfected, obstructive uropathy can develop. In community surveys in endemic areas, as many as 40% of children were found to have significant renal or ureteral abnormalities (or both).^{1,79,203} Hematuria and dysuria occur more commonly in children than in adults, presumably because they have heavier parasite loads. However, hydronephrosis, which develops more slowly, is seen more often in adults.^{95,98,131,178}

Bacterial urinary tract infection may coexist with urinary schistosomiasis, probably secondary to obstruction of urinary outflow.¹⁷⁸ Chronic infection can lead to renal failure. Obstructive uropathy, with or without incident or recurrent urinary tract infections, can lead to loss of renal function. Children with schistosomal infection also can have glomerulonephritis and nephrotic syndrome. Bladder cancer, when it occurs, typically develops in the setting of untreated, heavy chronic urinary schistosomiasis.

Genital Schistosomiasis

Studies have emphasized the genital tract as an important site of schistosomiasis in both men and women.^{29,107,149,150} In women, egg granulomas may be found in the cervix, uterus, or fallopian tubes.^{58,107,108,150} Cervical irritation and ulceration, vaginal bleeding, or ectopic pregnancy may develop. Genital schistosomiasis can be confused with cancer.¹⁹⁰ Adolescent boys may have involvement of the prostate and seminal

vesicles.^{107,153} Eggs were noted in semen from 43% of men in an area endemic for *S. haematobium*.¹⁰⁷ The main clinical finding is hematospermia,¹⁰⁷ which may occur with acute infection or during chronic disease. Approximately 48% of 10- to 12-year-old girls with heavy urinary *Schistosoma* infection report genital symptoms.⁸⁰ Girls with genital schistosomiasis can experience bloody vaginal discharge, genital itch, burning genital sensations, malodorous discharge, and nodular or ulcerated lesions.⁸⁰ On pelvic and colposcopic examination, older adolescent girls and young adult woman with urinary schistosomiasis can have rubbery lesions (containing viable ova) and grainy or sandy patch lesions (containing calcified ova) on mucosal surfaces.¹⁵¹ In females, genital schistosomiasis increases transmission of human immunodeficiency virus infection threefold to fourfold.^{139,176}

Intestinal Disease

Most children with intestinal schistosomiasis do not have intestinal symptoms.^{186,184} Thus even finding eggs in stool does not mean that symptoms are related to the schistosomiasis.⁷⁷ Nonetheless, both the small and large intestines may be involved with schistosomal disease. Irritation of the bowel wall from inflammatory reactions induced by eggs may lead to diarrhea that sometimes contains blood or mucus.^{34,35,184-186} Crampy abdominal pain and generalized malaise may occur. Endoscopy can reveal granular inflammation with hyperemic areas, ulceration, and hemorrhage. Polyps, which may develop around granulomas, may be identified by contrast radiography or endoscopy. Protein-losing enteropathy and blood loss can result in malnutrition and iron deficiency, especially in cases with significant small bowel disease. The role of schistosomiasis in malnutrition was illustrated by studies of mass chemotherapy, which resulted in improved nutrition and a lower prevalence of anemia.^{11,141,191}

Hepatosplenic Disease (Hepatomegaly, Splenomegaly, and Portal Hypertension)

The life-threatening complications caused by *S. japonicum* and *S. mansoni* are the result of eggs that remain in the venous vasculature and migrate back to the liver.²⁰ Egg burden seems to be the greatest predictor of hepatic involvement with schistosomiasis, but some link with human leukocyte antigen type has been suggested.^{127,129,170,205}

Children with compensated disease initially have few symptoms. These symptoms may include anorexia, malaise, and abdominal fullness.^{20,35,103,144,153,207} Children have hepatomegaly even without significant portal hypertension. The hepatomegaly generally is firm and either minimally tender or nontender. Splenic enlargement usually is noted as well. Liver function is affected only late in the course of hepatic schistosomiasis, so jaundice and liver enzyme elevations are unusual findings.

As fibrosis develops around eggs in the liver, portal hypertension ensues. Liver function usually remains intact, but esophageal varices can cause death during the late adolescent and early adult years.^{20,35,143} Ascites gradually develops during a period of years, and the spleen may become very large. Bleeding esophageal varices are a common cause of demise in individuals who had heavy schistosomal infections in childhood. Such patients may come to medical attention for melena or hematemesis. Initial episodes are well tolerated. However, with progressive liver decompensation, variceal bleeding can be fatal.

Children with severe hepatosplenic schistosomiasis do not grow as well as other children. Debate has ensued about whether this deficiency is due to a direct effect of the parasitic infection or poor nutritional intake caused by poor general health. Some data suggest that a decrease in insulin-like growth factor-1 activity is linked to hepatic schistosomiasis.¹⁴⁵ Extensive formation of hepatic granulomas may hinder the liver's structure and function in such a way that growth-promoting factors are not produced normally.

Pneumonitis and Cor Pulmonale

Sometimes, children initially have low-grade fever and cough as schistosome larvae migrate through their lungs. This condition can occur with an initial heavy infection (when eggs will not be detectable) or a heavy reinfection (when eggs will be detectable in urine or stool from the preceding underlying infection). This larval pneumonitis can be

manifested on lung examination as basilar rales and wheezing.^{43,168} Radiographs may show basilar mottling in the lung fields. Eosinophilia is a common occurrence with this type of pneumonitis. Resolution, even without treatment, usually occurs in 2 to 4 weeks. Similar symptoms also may be seen as a reactive pneumonitis when patients with heavy parasite burdens are treated.

In children with advanced hepatosplenic schistosomiasis and portal hypertension, eggs may bypass the liver and flow from the abdominal and pelvic veins into the small lung vessels. Localized granulomas form around eggs lodged in the lungs. Over time, children may be subject to fatigue, cough, and right-sided heart failure. Medical therapy stops the progress of disease and may decrease the ongoing inflammatory responses, but right-sided heart failure, after it is established, is not fully reversible.

Central Nervous System Involvement

Neurologic manifestations of schistosomiasis may be dramatic, even if not common.^{30,60,61,138,149,158,169} Worms do not always follow the typical routes described for urinary and intestinal schistosomiasis. On occasion, worms migrate to cerebral blood vessels. Production of eggs in that location can cause seizures and headaches in children.^{149,169} Sometimes, optic field defects and dysarthria are noted; these findings seem to result from localized space-occupying inflammatory reactions that develop around worms or eggs. Magnetic resonance imaging (MRI) evaluation reveals a mass or masses of multiple intensely enhancing nodules.¹¹⁶ Spinal fluid pressure may be elevated, and both protein concentrations and lymphocyte counts in spinal fluid may be increased. This cerebral schistosomiasis occurs more commonly with *S. japonicum* infection⁶¹ and is thought to develop in as many as 2% of infected children.

S. mansoni infection and, to a lesser extent, *S. haematobium* infection can produce eggs that embolize to the spinal cord. The eggs or associated granulomas can cause transverse myelitis. Paraplegia along with urinary and fecal incontinence often is the initial problem in children with spinal schistosomiasis.^{60,169}

Chronic or Recurrent Salmonellosis

In endemic areas, some children have salmonellosis and schistosomiasis concurrently and experience chronic low-grade fever, fatigue, malaise, and poor growth.^{71,102,103,155,164,215} Blood cultures frequently demonstrate *Salmonella* bacteremia, but stool may not contain these bacteria. Some children have chronic *Salmonella* bacteriuria. Sepsis and mortality are unusual findings despite these persistent bacterial infections. Relapse of the *Salmonella* infection occurs commonly unless the coexisting schistosomal infection is treated. The bacteria are thought to hide within the parasitic worms, where antibiotic penetration is poor, and thereby evade host defenses.

DIAGNOSIS

A clinical diagnosis of schistosomiasis should be entertained in the presence of typical clinical features. These features might be as obvious as painless hematuria in a child in a region endemic for *S. haematobium*, or portal hypertension may be noted late in the second decade of life in an otherwise healthy adolescent from an area known to be endemic for *S. mansoni* or *S. japonicum*.^{153,166} The other clinical findings described also should prompt the clinician to consider a diagnosis of schistosomiasis when the child has resided in or traveled through a *Schistosoma*-endemic area.¹⁸⁹ In traveling children, the index of suspicion must be particularly high because patients may be asymptomatic or have atypical symptoms, they may not have clear history of exposure to contaminated water, and parasitologic examination findings often are negative.^{19,153}

Outside endemic areas, reinfection is not expected. Thus a reasonable approach is to test all children, including asymptomatic children, who have returned or emigrated from an endemic area where they had potentially significant exposure to fresh water. Such testing would involve all travelers who swam in, waded in, or even touched suspicious water, and it could involve immigrants who have spent long periods in endemic areas. Certainly, any child outside an endemic area who has even a remote history of having had possible contact with cercariae and clinical findings suggestive of any form of schistosomiasis should be tested.

FIG. 229.3 Human schistosome eggs. (A) *Schistosoma mansoni*. (B) *Schistosoma japonicum*. (C) *Schistosoma intercalatum*. (D) *Schistosoma haematobium*. (From Mahmoud AAF, ed. *Schistosomiasis*. London: Imperial College Press; 2001.)

Testing is appropriate because even late therapy can favorably alter the course and outcome of schistosomiasis.

In some highly endemic areas, diagnostic testing is of limited feasibility, questionable reliability, or both, and curative medications are readily available. In such settings, establishing a proved diagnosis might be less necessary. For example, in a highly endemic setting, a urine paper strip test result positive for hematuria could provide sufficient suspicion of infection to warrant administration of specific antischistosomal therapy.²⁰⁶ In populations with known high rates of infection, mass treatment (without expensive diagnostic testing) is reasonable.

In established heavy infections, eggs usually are readily apparent on microscopic examination of urine or stool. For lighter infections, concentrating techniques are useful. Urine can be centrifuged and filtered to increase the yield of eggs. The result of urine examination is most likely to be positive when urine is voided at midday and when it is collected at the end of the urine stream. In the event of high suspicion and negative urine findings, bladder wall biopsy can be performed. The procedure usually is not necessary, however, because urine microscopy, especially with filtered or concentrated samples, generally is positive. Examination of multiple samples increases the yield.

The eggs of *S. haematobium* and *S. mansoni* are approximately 90 μ m in diameter, whereas the eggs of *S. japonicum* and *S. mekongi* are somewhat smaller. As demonstrated in Fig. 229.3, identification of species is aided by observation of the spine—small for *S. japonicum* and *S. mekongi*, at one end for *S. haematobium*, lateral for *S. mansoni*, and broad at each end for *S. intercalatum*. Eggs usually are detectable in voided urine. Plain radiographs might demonstrate some calcification in the bladder wall around chronic granulomas. Cystoscopy, if it is performed, reveals bladder wall hyperemia and, subsequently, nodular lesions and fibrosis that give rise to “sandy patches” on the bladder wall. Granulomas may protrude from the bladder wall into the lumen. Both edema and granulomas may be seen obstructing ureteral orifices.

In light infections, examination of stool or urine samples may not reveal ova because of intermittent or low-volume shedding. Thus negative stool or urine test results do not adequately rule out intestinal schistosomiasis.^{20,153} When stools repeatedly are negative for ova, rectal biopsy may be performed. Samples may be obtained by random punch biopsy, but the yield is increased when samples are taken from inflamed sites under direct visualization. Eggs are detected in unstained smears made by pressing the tissue sample between a coverslip and a glass slide, but eggs also can be seen with standard histologic stains.

Nonviable eggs may be excreted for months or years after therapy has been successful. With good medical treatment, eggs usually are not viable when they are passed more than a week after the initiation of therapy. With ineffective treatment or reinfection, however, viable eggs may continue to be passed. On microscopic examination, living ova contain transparent miracidia within the egg, which often are motile. For further documentation of their viability, the eggs may be hatched by placing them in fresh water exposed to light for 20 minutes; observation with a hand lens then can reveal swimming miracidia.

Serologic tests may be needed in acute infection, which may occur before the eggs are excreted or with eggs in ectopic locations.^{78,195} For travelers with limited exposure and the likelihood of having either an

acute or a limited chronic infection, serologic examination is the main diagnostic tool. A common screening serologic test is the Falcon assay screening test—enzyme-linked immunosorbent assay (FAST-ELISA) using *S. mansoni* adult worm microsomal antigen.¹⁹⁴ This test also cross-reacts with *S. haematobium* but is less sensitive for *S. japonicum* or *S. mekongi* infection. Indirect hemagglutination tests are 70% to 80% sensitive for Katayama syndrome, and ELISA tests do not add to the diagnostic value when an indirect hemagglutination test has already been positive.¹⁵⁹ The species can be confirmed by use of an immunoblot assay (enzyme-linked immunotransfer blot).¹⁹⁵ An immunoblot assay also is available for *S. japonicum*. New tests hold promise in easily identifying antischistosomal antibodies in serum²¹⁶ and urine.³⁶ Antigen-detection assays may be helpful.^{3,206} In a small study of European travelers with acute schistosomiasis from Rwanda, serum DNA detection performed better than parasitologic and serologic tests in confirming the diagnosis.³⁹

Ultrasonography is the main imaging procedure used in schistosomiasis.⁷⁹ It can document involvement of the portal and urinary tracts and, in selected cases, be diagnostic of schistosomiasis. Ultrasonography can identify bladder polyps, ureteral dilation, hydronephrosis, and calcifications within the urinary tract. When resources are available, an ultrasound evaluation of the urinary tract should be performed in any child found to be infected with *S. haematobium*. Ultrasonography can be readily implemented in clinical settings in developing countries to follow lesions of urinary schistosomiasis.²¹ For children with persistent urinary symptoms (i.e., dysuria, suprapubic pain, and hematuria) despite having received good medical treatment, cystoscopy should be considered, in part to screen for bladder cancer. Other radiographs and tests of renal function and excretion generally are not indicated unless the ultrasound evaluation reveals significant urologic disease.

Portal ultrasonography is the imaging study of choice for hepatic involvement. The presence of periportal fibrosis with thickening of the portal tracts and vein walls (so-called clay pipestem or Symmers fibrosis) correlates with parasite burden and hepatic disease. In experienced hands, schistosomiasis can be distinguished reproducibly from cirrhosis and other chronic liver diseases.

MRI is helpful in diagnosing neuroschistosomiasis.⁶¹ A variety of cerebral changes may be identified; although not specific for *S. japonicum* neuroschistosomiasis, large masses containing enhancing nodules may be seen in the brain.^{61,116} Focal cerebral white matter hyperintensities and hyperintense basal ganglia may be seen in children with hepatosplenic schistosomiasis even when they do not have overt neurologic symptoms.¹²² Spinal schistosomiasis, usually caused by *S. mansoni* or *S. haematobium*, can cause spinal pseudotumors with heterogeneous enhancement as well as signal changes extending up and down the spinal cord from the thoracic level.^{48,81}

TREATMENT

Optimal treatment of schistosomiasis varies with the stage of the disease. Cercarial dermatitis resolves spontaneously and requires no antiparasitic treatment. Oral antihistaminic agents, however, may be given for severe itching. Medical therapy for schistosomiasis caused by the human

schistosomes is effective and well tolerated, without significant complications. No good medical reason exists to allow schistosomiasis to go untreated. The cost of therapy, however, is a limiting factor in resource-limited areas of the world. Several medications can be considered for curative treatment.

Praziquantel, a mixture of stereoisomers of pyrazinoisoquinoline ring structures, is a broad-spectrum oral anthelmintic agent that is effective against each of the human schistosome species.³³ The mechanism of action was thought to involve unmasking of parasite antigens with subsequent killing by the host immune response.²⁵ However, patients with acquired immunodeficiency syndrome respond well to praziquantel, raising questions about this hypothesis. Praziquantel is given in divided doses on a single day as full curative treatment. For infection with *S. haematobium*, *S. mansoni*, and *S. intercalatum*, the dose is 40 mg/kg in two divided doses given on the same day. For children infected by *S. japonicum* or *S. mekongi*, the recommended dose had been 60 mg/kg in three divided doses given on the same day,^{4,6,160} but recent evidence and recommendations suggest that 40 mg/kg is appropriate for infection with all species of schistosomiasis in people of all ages.^{33,142,222} Heavily infected children sometimes experience nausea, vomiting, and abdominal cramping with treatment. Rare side effects, including headache, pruritus, bloody stools, and fever, are transient and resolve within 1 to 2 days after the initiation of treatment. Because praziquantel primarily kills mature adult worms,⁷⁴ repeat testing with or without a second course 6 to 12 weeks later is recommended for the treatment of acute infection.¹⁵⁸ In endemic area settings of school-based and community-based mass treatment, adding a second dose of praziquantel 2 to 8 weeks after the initial dose improves reduction in egg counts.¹⁰⁰ Praziquantel is effective in more than 90% of treated children. Some studies suggested that resistance may be emerging.^{33,110,111} However, those studies were performed in areas with frequent reinfection and with high parasite burden. Thus the poor response may have been because juvenile forms are not as susceptible to praziquantel. Ongoing work suggests that praziquantel is still effective in endemic areas.^{33,132,172} Studies from nonendemic areas also continue to demonstrate excellent efficacy.²⁰⁷ In addition to curing infection, treatment with praziquantel is associated with improved growth and reduction in anemia.⁴⁶ In endemic areas with high rates of infection, school-based and community-based (when many children in the area do not regularly attend school) treatment strategies (without confirmatory diagnostic testing) are effective; cost issues, however, raise concerns of program sustainability.^{68,100} Praziquantel not only decreases infection rates but also reduces subsequent reinfection in some¹⁷¹ but not all¹³⁷ areas.

An alternative treatment effective only against *S. mansoni* is oxamniquine, a tetrahydroquinoline compound.¹⁸² The mechanism by which this agent acts is unknown. The effective dose has varied with the geographic origin of the schistosomal infection, but some resistance has been reported. Current recommendations are that children treated with oxamniquine be given 40 to 60 mg/kg divided into two doses administered on 1 day or four separate doses given during the course of 2 days. Mild side effects include nausea, headache, and fever. Seizures are a rare side effect, so administration of this medication should be avoided in children with seizure disorders. Cure rates of more than 90% are reported with oxamniquine.

Metrifonate is an organophosphate compound that causes paralysis of the parasite. It is 70% to 80% effective against *S. haematobium* when used at a dosage of 10 mg/kg orally once every 2 weeks for 6 weeks. It does decrease the child's own plasma and erythrocyte cholinesterase activity, but actual cholinergic symptoms seldom occur. This medication is less expensive than the other options, but it generally is not used when praziquantel is available.

Further exploration of new antischistosome agents and medication combinations continues.^{54,93,214}

Medical therapy usually is effective for children with schistosomiasis,¹⁶¹ even with advanced disease.^{112,163,181,217} Clear improvement in the patient's disease burden occurs when treatment is given. Even established uropathy and portal hypertension often are reversible.^{114,163,181} Surgical procedures usually are reserved for children with complications related to long-term infection, such as persistent portal hypertension. Propranolol prophylaxis and sclerotherapy or banding can reduce rebleeding from esophageal

varices.⁵⁵ Some cases require surgical decompression of portal hypertension. Splenorenal shunts are associated with high rates of hepatic encephalopathy. Comparative studies suggest that in experienced hands, esophagogastric devascularization with splenectomy is the procedure of choice.^{62,70}

Systemic steroids may be useful for severely ill children with Katayama fever or severe larval pneumonitis. Treatment of neuroschistosomiasis often involves a combination of corticosteroids and praziquantel, with surgery being reserved for those with medullary compression or hydrocephalus.¹⁵⁸ The role of steroids is significant^{60,65} but controversial³¹ and incompletely tested. Some experts suggest that glucocorticoids be started before the initiation of antiparasitic therapy, to prevent increased inflammatory responses triggered by dying worms.¹⁵⁸ Phenobarbital and phenytoin (but not levetiracetam) can alter metabolism of praziquantel; when used for neuroschistosomiasis-induced seizures, these medications might prompt upward adjustment of the praziquantel dose.¹⁵⁸ Corticosteroids have not been proved effective treatments in other forms of the disease.

PREVENTION

Schistosomiasis has been considered controllable or even eradicable for nearly 100 years.¹⁵⁶ However, control is still not quite within reach. Further multifaceted interventions are needed if we are to be rid of the scourge of schistosomiasis.^{85,156} Nonetheless, successful programs in some countries such as Egypt and Brazil demonstrate that control and elimination of schistosomiasis are feasible.¹⁶⁷

Travelers and expatriates in endemic areas can prevent disease by limiting exposure to infectious fresh water. In endemic areas, they should avoid swimming in fresh-water streams and lakes. In addition, the cercariae can be eliminated by chlorination or by allowing water to settle for 24 hours before bathing or washing.

The use of effective medical therapy coupled with improved urine and stool hygiene has the potential to eradicate schistosomiasis from endemic areas.²⁰⁸ Elimination of the snails that serve as intermediate hosts also would be effective, but attempts at implementation of programs administering molluscicides have been unsuccessful to date. Historically, national control programs in China focusing on snail control, sanitation, and improved water supplies led to sustained reductions in infection rates, even apart from the influence of chemotherapy.^{198,212} For specific populations, health education can lead to significant favorable changes in knowledge about the illness, water-exposure activities, and reinfection rates in school-aged children.⁷⁶ Recently, control efforts have focused on mass chemotherapy, with particular emphasis on school-based therapy.^{11,77,141,144,208} Similar treatment of preschoolers, especially combined with nonpharmacologic control efforts, is also effective.^{136,183} Treatment programs in which the entire school-aged population is treated, typically with praziquantel, have resulted in overall improvement in levels of nutrition and in a reduction in the prevalence of anemia. In areas where reinfection commonly occurs, however, the effects of mass treatment programs are of limited duration, and treatment must be repeated every 6 months to 1 year. Sadly, only about 10% of persons who could benefit from antischistosomiasis treatment are able to receive it each year.⁸⁵ Sustainability of national control programs and of favorable outcomes remains challenging in Africa.^{59,69,86,90}

Several studies suggest that artemisinin derivatives can prevent development of infection and decrease the worm burden in those exposed to *S. mansoni* and *S. japonicum*.^{109,115,157,197} With ongoing exposure to cercariae, prophylactic artemether or artesunate may be given as a 6 mg/kg dose every 1 to 2 weeks.¹¹⁵ However, these medications are less effective for chemotherapy than is praziquantel.^{23,49,158} probably because parasitologic activity is limited to the juvenile forms. Furthermore, the public health role of chemoprophylaxis in the prevention of infection has not been established.¹⁵⁸

Immunization of experimental animals with irradiated cercariae can prevent experimental schistosomiasis.¹⁷⁹ Thus development of a vaccine to prevent human schistosomiasis is theoretically possible. Several potentially protective antigens have been identified on schistosomes, and they are being used as targets for vaccine development. Animal studies with the Sm-p80 vaccine show promise with some favorable

effects on worm reduction, worm egg production reduction, and decreased acute schistosomiasis.¹⁷⁵ Murine studies with Sm-TSP-2 show some efficacy, and chimerization with a hookworm vaccine antigen (Na-APR-1) increases the antischistosomal effectiveness of the vaccine.¹⁴⁸ Human studies are in progress with Sh-28-GST for *S. haematobium*¹⁵² and Sm-14 for *S. mansoni*.^{27,193} However, the correlates of protective immunity in humans are not well defined.^{27,213} Vaccines related to several *S. japonicum* antigens also are being studied in animals, but efficacy is limited.^{130,159,220} No vaccine is yet ready for clinical use,^{16,73} but progress continues.⁶⁴

SUBSECTION V Arthropods

230

Arthropods

Jan E. Drutz

Arthropods comprise nearly three-fourths of the world's animal species. Although some arthropods are capable of producing damage to agriculture and homes and others serve as reservoirs, hosts, and vectors of human and animal pathogens, most have no significant impact in causing human disease.⁷⁶ However, among the more significant diseases transmitted to humans by arthropods are Chagas disease, malaria, dengue, and bubonic plague. In the United States, ticks transmit more vector-borne diseases caused by bacteria, rickettsia, viruses, and protozoa than do any other species.

TICKS

Ticks, mites, spiders, and scorpions all belong to a class of arthropods known as Arachnida. Two of three families of ticks belonging to this class contain species capable of transmitting pathogens to humans. Ixodidae, the hard tick family, and Argasidae, the soft tick family, serve

as both vectors and reservoirs for many rickettsiae (Table 230.1). By use of a fluorescent technique, these rickettsiae can be identified in the tick hemolymph.

However, no rapid laboratory test is currently available to diagnose early-stage rickettsial disease. Possible confirmation of a clinical diagnosis can be obtained by polymerase chain reaction (PCR) testing or immunohistochemical staining of punch biopsy specimens. The expertise required is limited, available only at certain reference laboratories or the Centers for Disease Control and Prevention (CDC). A number of other tests have been used, but the time to diagnostic confirmation can be a disadvantage. Based on the physician's clinical judgment and expertise, treatment of the patient should not be delayed.

Hard ticks are so named because of their scutum, a dorsal sclerotized shield. Owing to the limited scutum coverage of the female, she is more capable of becoming engorged with blood than is the male, a factor significant in the reproductive process. During feedings, these ticks

TABLE 230.1 Human Infectious Diseases for Which Ticks Are a Vector

Disease	Agent
Relapsing fever	<i>Borrelia duttonii</i>
Q fever	<i>Coxiella burnetii</i>
Tularemia	<i>Francisella tularensis</i>
Queensland tick typhus	<i>Rickettsia australis</i>
Fièvre boutonneuse	<i>Rickettsia conorii</i>
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>
Asian tick typhus	<i>Rickettsia sibirica</i>
Colorado tick fever	Arbovirus
Encephalitis	Arbovirus
Lyme disease	<i>Borrelia burgdorferi</i>
Human monocytic ehrlichiosis	<i>Ehrlichia chaffeensis</i>
Human granulocytic ehrlichiosis	<i>Ehrlichia</i> spp.
Babesiosis	<i>Babesia microti</i>

remain attached to the host for hours or days at a time.^{21,66} Three genera of Ixodidae are known to transmit disease to humans in the United States: *Amblyomma*, *Dermacentor*, and *Ixodes*.⁶⁷

Soft ticks have no scutum and tend to live for long periods, often surviving for years without eating. Both the nymph form and the adult tick have a tendency to eat often but for brief periods often lasting less than 30 minutes.^{21,66} Of the family Argasidae, only ticks of the genus *Ornithodoros* are known to transmit pathogens to humans in the United States.⁶⁷ Specifically, they are the vectors of tick-borne relapsing fever.

Local reaction from tick bites appears to be mediated by complement. The reaction from these bites may persist and subsequently develop into a so-called tick bite granuloma. Systemic reactions such as fever, chills, nausea, vomiting, abdominal pain, and headache can be associated with tick bites.

As noted, tick-borne diseases can result from infection with pathogens that include bacteria, rickettsia, viruses, and protozoa.⁶⁸ The major tick-borne diseases occurring in the United States include tick paralysis (discussed here), tularemia (see Chapter 132), tick-borne relapsing fever (Chapter 195), Lyme disease (Chapter 140), Colorado tick fever (Chapter 185), Rocky Mountain spotted fever (Chapter 195), ehrlichiosis (Chapter 195), and babesiosis (Chapter 219).

Tick-borne rickettsial diseases are clinically similar yet epidemiologically and etiologically distinct illnesses. In the United States, they include Rocky Mountain spotted fever, human monocytotropic (or monocytic) ehrlichiosis, human granulocytotropic (or granulocytic) anaplasmosis (formerly known as human granulocytotropic ehrlichiosis), *Ehrlichia ewingii* infection, and other emerging tick-borne rickettsial diseases.¹³ Mediterranean spotted fever, a tick-borne disease caused by *Rickettsia conorii* (Chapter 195), is found almost exclusively in the Mediterranean area.

Since 2007, five tick-borne diseases have been reported as occurring most often in the United States: Lyme disease, Rocky Mountain spotted fever, ehrlichiosis, anaplasmosis, and babesiosis. Lyme disease, babesiosis, and anaplasmosis are all transmitted by the *Ixodes scapularis* tick. Among contributing factors possibly accounting for the prevalence of these diseases are an increase in the number of ticks, geographic spread, climatic change, improved physician awareness and reporting, and improved local and state surveillance.²⁴

Tick Paralysis

Tick paralysis is a neurologic syndrome characterized primarily by an ascending flaccid paralysis. The etiologic agent is a potent neurotoxin produced by an attached, engorged tick.³⁴ A well-known disease of animals, it was reported to occur in humans in North America first in 1912.⁷² Most cases have been reported in the Pacific Northwest and Rocky Mountain states, during spring and summer.⁶⁸ It occurs more frequently in children than in adults, especially in girls between 2 and 5 years of age. Patients present with paresthesias and leg weakness, but

have no fever. Within 1 to 2 days, weakness in the legs ascends to the trunk musculature, resulting in an inability of the patient to sit or walk without assistance.³⁴

Numerous genera of ticks are known to be associated with tick paralysis. In North America, *Dermacentor andersoni* (wood tick) and *Dermacentor variabilis* (dog tick) are the primary species responsible.⁴⁸ In Australia, the ticks implicated most commonly are *Ixodes holocyclus* and *Ixodes cornuatus*. Both male and female adults, as well as immature ticks, have been implicated as vectors for this disease.

Pathogenesis

Tick paralysis is thought to be caused by a neurotoxin (holocyclotoxin) produced in the tick's salivary glands.⁴⁶ It usually is released by gravid female ticks at the site of attachment, generally the scalp. The neurotoxin is a protein with temperature-dependent activity.¹⁹ The exact mechanism and location of the toxin's action are not known but may include decreased entry of calcium into motor nerve terminals or interference with presynaptic excitation–secretion coupling, which leads to a reduction of acetylcholine release at the motor end plate.

Investigations in children with tick paralysis have implicated peripheral nerve dysfunction, attributable to somewhat site-specific diminished nerve conduction velocities.^{41,69} Compound muscle action potentials that are abnormally low or low-normal in amplitude when the patient has maximal neurologic deficits, generally are reversed rapidly once the tick is removed.⁴⁸ Swift and Ignacio⁶⁹ postulated that the major effect of the toxin is to prevent depolarization in the terminal portions of the motor neurons.

Clinical Manifestations

Onset of tick paralysis usually occurs 5 to 7 days after the female tick attaches to the skin. Until mating occurs with the male, engorgement of the female tick is relatively limited. Mating leads to rapid engorgement, fertilization of the eggs, and production of the neurotoxin. In turn, production of neurotoxin coincides with initial paralytic symptoms, and continual feeding accelerates production of toxin, accounting for rapid clinical deterioration. When the female becomes engorged, she disengages from the skin to deposit her eggs.³⁴

Ascending paralysis, along with hyporeflexia or areflexia, progresses to arms, and then to the bulbar structures involved in speech, swallowing, and facial expression.³⁴ Sensory function usually is spared, and the sensorium remains clear.⁶⁸ Alternatively, the disease can present as acute ataxia without muscle weakness.⁴⁹ Nystagmus, strabismus, and seizures may occur.⁴¹ After tick removal, symptoms tend to resolve within several hours or days. Left untreated, tick paralysis can be fatal, with reported mortality rates of 10% to 12%.⁶³

Routine laboratory tests are not helpful in establishing the diagnosis. The white blood cell count, urine analysis, cerebrospinal fluid, and erythrocyte sedimentation rate are usually normal.

Diagnosis

The diagnosis of tick paralysis can be established when the patient has the typical clinical picture and then improves rapidly after tick removal. A fine-toothed comb can aid in the detection of ticks attached to the scalp. The differential diagnosis of tick paralysis includes Guillain-Barré syndrome, botulism, poliomyelitis, myelitis, spinal cord neoplasm, syringomyelia, and porphyria. Botulism is characterized by slow, descending paralysis involving cranial nerves first, along with a usual extraocular palsy and large, poorly reactive pupils.³⁴

The neurologic impairment caused by the *I. holocyclus* tick in Australia is more severe than that caused by *Dermacentor* spp. in North America. With exposure to *I. holocyclus* neurotoxin, the weakness and bulbar symptoms often intensify during the first 24 to 48 hours after tick removal. Clinical recovery is much slower than with *Dermacentor*-related paralysis. *I. holocyclus* antitoxin must be administered before removal of the ticks, and a longer observation period is required.³⁴

Treatment
